As the s, d and f sub-shells start to fill, atoms gain a net electron spin. The crystal structure distorts to permit adjustment of interatomic distances. The crystal energy is lower if two sets of interatomic distances are provided, and atoms with antiparallel spins are permitted to maintain a closer approach than atoms with parallel spins. Classical examples of this type of spin interaction are the formation of the hydrogen molecule and the sign of the Slater[1] exchange integral. The f.c.c. structure does not provide two sets of interatomic distances. Every atom has nearest neighbours which are nearest neighbours of each other. No assignment of spins can satisfy the requirement of maintaining different interatomic distances for parallel and antiparallel interaction. The h.c.p. structure, when c/a is less than the theoretical value for closest packing 1·633, permits nearest neighbours to have antiparallel spins and next nearest neighbours to have parallel spins. Six nearest neighbours occupy the corners of a trigonal prism at a distance less than the lattice parameter 'a'. Next nearest neighbours occupy the corners of a hexagon at a distance equal to the lattice parameter 'a'. The h.c.p. structure with c/a less than 1·633 is found where metal atoms have a weak net spin. The energy gained in providing two sets of interatomic distances makes up for the energy lost in a lower packing density and lower symmetry. Weak net spins occur when shells just begin to fill and when they are almost filled. The scandium and titanium groups of metals have this structure. They represent the low net spin as the d-shell begins to fill. It occurs again in the almost filled d-shells with the metals technetium, ruthenium, rhenium and osmium. The structure is also observed among early $4f$ metals lanthanum to samarium and the late $4f$ metals gadolinium to thulium. All these h.c.p. metals have c/a ratios less than 1·633. Two metals, zinc and cadmium, have c/a ratios greater than 1·85. This large departure has been explained on the basis of dp^2 hybrids[2].

The net spin reaches its maximum value when the sub-shell is half-filled. The alkali metals, lithium to caesium, the refractory metals of the titanium, vanadium and chromium groups and europium have half-filled s, d and f shells, respectively. These metals crystallize in the b.c.c. structure. Zener[3] observed the tendency of the d sub-shell metals of high net electron spin to crystallize in a structure which permits nearest neighbours to have antiparallel spins. He explained how the b.c.c. structure fulfilled this requirement. Each atom in the b.c.c. structure is surrounded by eight nearest neighbours located at the corners of a cube. Next nearest neighbours are located at the centre of six adjacent cubes sharing the cube faces. The packing density is now about 9 per cent less than in the f.c.c. structure. The energy saved in providing two sets of interatomic distances for parallel and antiparallel electron spin interactions more than compensates for the lower packing densities.

It is a matter of conjecture whether or not the requirement of two sets of interatomic distances to accommodate parallel and antiparallel spin interaction requires a spin ordering in the structure. Neutron diffraction investigations of such systems have been discussed extensively[4]. Briefly, attempts to see spin ordering in b.c.c. elements by neutron diffraction have failed. However, the question remains whether the resonance frequency of exchange is too rapid to be resolved by neutron diffraction techniques.

In summary, the crystal structures of metallic elements possessing a net electron spin have their lowest energy when in a structure which provides a closer approach for atoms with antiparallel net electron spin than for atoms with parallel spin. As the s, d and f sub-shells fill, the equilibrium crystal structures follow the cyclic pattern f.c.c.–h.c.p.–b.c.c.–h.c.p.–f.c.c. When the sub-shells are empty or completely filled and the net spin is zero, the f.c.c. structure is preferred. When the net electron spin reaches a maximum, metallic elements tend to assume the b.c.c. structure. For intermediate values of net spin, they prefer the h.c.p. structure with c/a less than the theoretical value of 1·633. Exceptions to the rule occur among the alkaline earth metals, the actinides, and the lighter elements lithium, sodium, manganese and iron. In general, however, metals follow the cyclic pattern as closely as the anions follow the Hume-Rothery 8-N rule.

METALLURGY

Formation of Intergranular Voids and Cracks in an Irradiated Austenitic Steel tensile-tested in the Temperature Range 650°–850° C

THE elevated temperature embrittlement induced in austenitic steels by neutron irradiation is now well known[1,2]. Characteristic features are the intergranular mode of fracture in a tensile test and the marked reduction

in the non-uniform elongation. Barnes[3] has reported work by Pfeil and Barton which suggests that the (n,α) reaction of thermal neutrons with the boron-10 in the steel is responsible.

In the case of beryllium containing irradiation-induced helium in an atomic concentration of $\sim 10^{-5}$, the bubbles which precipitate at elevated temperatures can grow by vacancy absorption if a hydrostatic tensile stress is applied and maintained in excess of some critical value which depends on the bubble size[4]; those bubbles sited on grain boundaries grow most readily into holes, linking up to form interconnected fissures, and in this way lead to intergranular failure at reduced elongation in a hot tensile test.

Despite the low atomic concentration of helium in irradiated austenitic steels (about 10^{-7}), Barnes[3] has now deduced that the same mechanism would account for the extent to which irradiation reduces their elevated temperature ductility, assuming that the helium produced from boron-10 can reach the grain boundaries. Rowcliffe[5] has observed bubbles 60 Å in diameter at the grain boundaries of 20Cr–25Ni–Ti steel irradiated at 625° C, and found that in subsequent tensile tests at 750° C those in the gauge-length grew up to 600 Å in diameter.

However, there has so far been no direct indication of the way in which irradiation promotes intergranular parting in austenitic steels, primarily because the characteristic metallographic features occur very close to (within 0·1 mm of) the fracture surface. It has now been possible to reveal these by careful attention to the preparation of specimens.

I have examined 20Cr–25Ni–0·7Nb strip tensile specimens which had been irradiated at 750° C for 1,300 h to a thermal neutron dose of $3{\cdot}5 \times 10^{20}$ *nvt*, and pulled to rupture in argon at 3×10^{-4} sec^{-1} (at 750° C and 850° C) and $1{\cdot}7 \times 10^{-5}$ sec^{-1} (at 650° C and 750° C). In each instance the ductility of the irradiated specimen was reduced compared with that of the corresponding unirradiated thermal control. Electron microscopy using thin foils showed that the unstrained portions of the tensile-heads from the irradiated specimens contained gas bubbles at grain boundaries. Most of these were 50–100 Å in diameter, but occasionally 100–200 Å diameter bubbles were observed (Fig. 1); the number of bubbles per unit area of grain boundary surface was estimated to be of the order of 10^8 cm^{-2}. If the bubbles contain helium at a pressure $p = 2\gamma/r$, and the surface tension (γ) is assumed to be 10^3 dynes cm^{-1} and the mean bubble radius (r) 50 Å, then with a mean grain size of 30μ the number of bubbles could account for only about 1/100 of the gas produced by the boron-10 (n,α) lithium-7 reaction. A search for bubbles was made in thin foils prepared from the gauge lengths, but the high dislocation density made observation difficult, and the presence of gas bubbles was not established. (The area immediately adjacent to the fracture could not be studied by this method.)

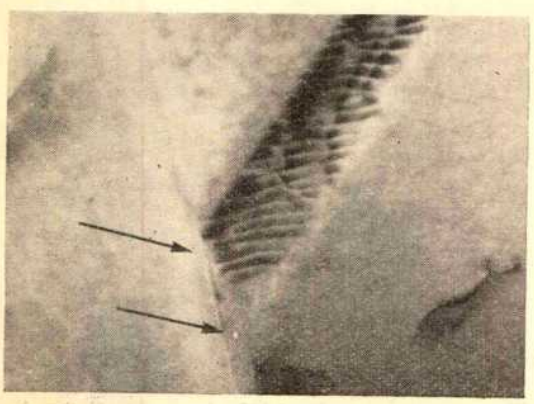

Fig. 1. Thin foil from tensile-head of specimen irradiated at 750° C. Note bubbles at grain boundary. (×50,000)

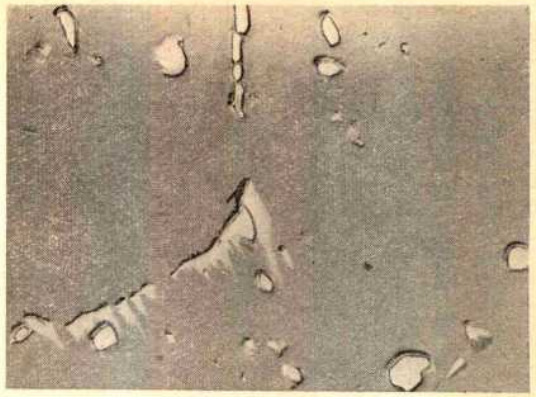

Fig. 2. Replica of electro-polished surface, irradiated specimen slowly strained at 650° C, area within 0·10 mm of fracture. (×5,000)

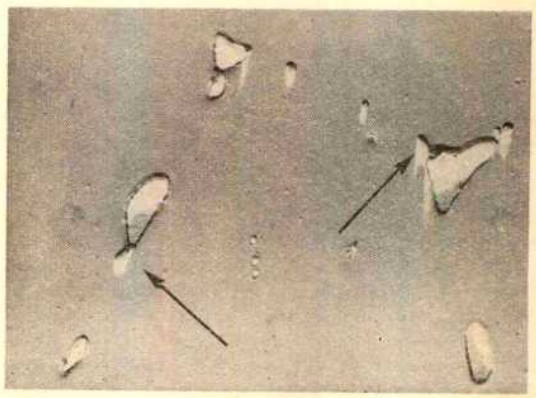

Fig. 3. Replica of electro-polished surface, irradiated specimen slowly strained at 750° C, area within 1 mm of fracture. (×8,000)

Little or no cracking was observed optically in the fast-strain specimens, except in the irradiated specimen tested at 750° C, which showed intergranular cracking limited to within 0·1 mm of the fracture. Intergranular failure was more marked in the slow-strain specimens. Briefly, the irradiated specimen tested at 650° C showed little plastic deformation and a few narrow intergranular cracks within 0·1 mm of the fracture, whereas the corresponding control showed plastic deformation and wide cracks up to 4 mm from the fracture. The irradiated specimen slowly-strained at 750° C showed plastic deformation near the failure but negligible cracking; the corresponding control showed marked necking and wide intergranular tears up to 0·5 mm from the fracture.

A light electro-polishing technique was developed for revealing the presence of intergranular precipitates, fine cracks and holes in the tensile specimens. The specimens were mechanically polished and then electro-polished in chromic-acetic electrolyte[6] at 18 V for 5 sec, which removed the surface layer to a depth of about 0·25μ; this treatment leaves the carbides in relief and the sigma FeCr slightly depressed below the surface.

Two-stage replicas taken from the irradiated fast-strain tensile specimens revealed the presence of holes of 0·1–0·2μ diameter at grain boundaries, sometimes attached to precipitates, together with micro-cracks, about 1μ long, in the region within 0·1 mm of the fractures. These features were less evident further away from the fracture, and were absent in the tensile heads.

The slow-strain irradiated specimen tested at 650° C showed similar holes and micro-cracks near the fracture, but in this instance the process of intergranular failure

was more clearly seen. Micro-cracks occurred at grain boundary precipitates, together with chains of discrete holes which were elongated in the direction of the boundary (Fig. 2). The slow-strain specimen tested at 750° C again showed grain boundary holes, some extending from precipitates along the boundary (Fig. 3), but no micro-cracks were seen. These features were not seen in the tensile-heads of the irradiated specimens or in any of the thermal controls.

The observations of grain boundary holes 0·1–0·2μ diameter are direct evidence that irradiation has affected the failure mechanism and suggest that, in the irradiated material, stress-induced growth of gas bubbles is responsible. The initial radius r_i of a helium-filled bubble which can grow indefinitely by vacancy absorption under a given critical uniaxial stress σ_{xc} is directly dependent on the surface energy γ of the material[3,4]. For a bubble within a grain:

$$r_i = 4\gamma/\sqrt{3}\sigma_{xc} = 2{\cdot}31\ \gamma/\sigma_{xc} \text{ (ref. 3)}$$

Furthermore, a bubble at a grain boundary is also acted on by the tension of the grain boundary. The application of a tensile stress σ_x normal to the boundary will tend to alter the bubble shape and the equilibrium of forces at the periphery of the bubble. The peripheral grain boundary tension on a bubble of radius 10^{-6} cm is of the same order of magnitude as that of the tensile stress acting on the bubble; the effective hydrostatic component of the tensile force is therefore greater than $\sigma_x/3$ (for a bubble within a grain) and tends towards σ_x, that is, $r_i \rightarrow 0{\cdot}77\ \gamma/\sigma_{xc}$ (ref. 4).

If the surface tension at the helium bubbles is as low as 10^3 dynes cm^{-1} and σ_{xc} is approximately equal to the tensile strength (as little necking occurred), then the calculated values of $2r_i$ for grain boundary bubbles range from ~ 80 Å (for the slow-strain test at 650° C, ultimate tensile strength = 1,950 kg cm^{-2}) to ~ 230 Å (for the fast-strain test at 850° C, ultimate tensile strength = 678 kg cm^{-2}). This implies that stress-induced growth of the bubbles observed is feasible, assuming the foregoing conditions.

The observation that micro-cracks form near the fractures of the irradiated material, instead of blunt fissures as in the slow-strain controls, suggests that the grain boundary cohesion of the material is lowered by irradiation, as would result from segregation to the boundary of impurity atoms which lower the energy of free surfaces (compare with the behaviour of sodium in aluminium–magnesium alloys[7]). Both helium and lithium ions are produced in steel irradiated with thermal neutrons, and Higgins and Roberts[8] have recently shown that at concentrations of 10^{-5} these elements can separately cause embrittlement in this steel at 750° C, the helium exhibiting the larger effect. The combination of helium and lithium together may be more effective than either element alone in causing embrittlement, if the lithium can segregate to the free surfaces of helium-filled bubbles and reduce the stress required for these to grow into cracks.

CHEMISTRY

Interior Morphology of Bulk Polypropylene

As the result in recent years of the growth and identification of lamellar single crystals of various polymers, produced both by dilute-solution methods and by melt crystallization of thin films, older concepts of the structure and texture of bulk crystalline polymers have been undergoing change[1]. Indications that bulk samples of partially crystalline polymers also contain lamellar-like crystals have come from electron microscope examinations of fracture surfaces[2], and of fragments[3,4] of bulk polymers dispersed by means of a nitric-acid digestive treatment[5].

Striking evidence in favour of the concept that bulk polymers may also consist largely of lamellar-like crystals has been obtained from a study of the crystallization behaviour of isotactic polypropylene. Samples of this material were first compressed in a high-pressure mould to 60,000 lb./in.² and then held at a temperature of 325° C for 3 h. This temperature is about 30° C higher than the melting point of polypropylene at the pressure of 60,000 lb./in.². The pressed sample was brought to a temperature of 248° C (about 47° C supercooling) and held at this temperature for 140 h. The temperature was then slowly reduced to room temperature, the pressure returned to atmospheric, and the sample removed. The sample, in the form of a solid rod 0·25 in. in diameter and 3·5 in. long, appeared to be in a highly brittle state and some powdering occurred during its removal from the mould.

The sample was cooled to liquid nitrogen temperatures and later fractured at these temperatures in order to inhibit plastic flow. After fracture, the fracture surfaces were examined by light microscopy, then replicated, and the replica examined by transmission electron microscopy. The light microscope examination showed a spherulitic structure with the size of the spherulites being of the order of 100μ. It was also observed that both inter- and intra-spherulitic fractures had occurred.

An electron micrograph of a replica of a portion of the fracture surface is shown in Fig. 1. Numerous, somewhat

Fig. 1. Electron micrograph of replica of fracture surface of a bulk polypropylene sample moulded at 60,000 lb./in.² and held for 140 h at 248° C

Fig. 2. Higher magnification electron micrograph of portion of fracture surface of polypropylene sample moulded at 60,000 lb./in.² and held for 140 h at 248° C

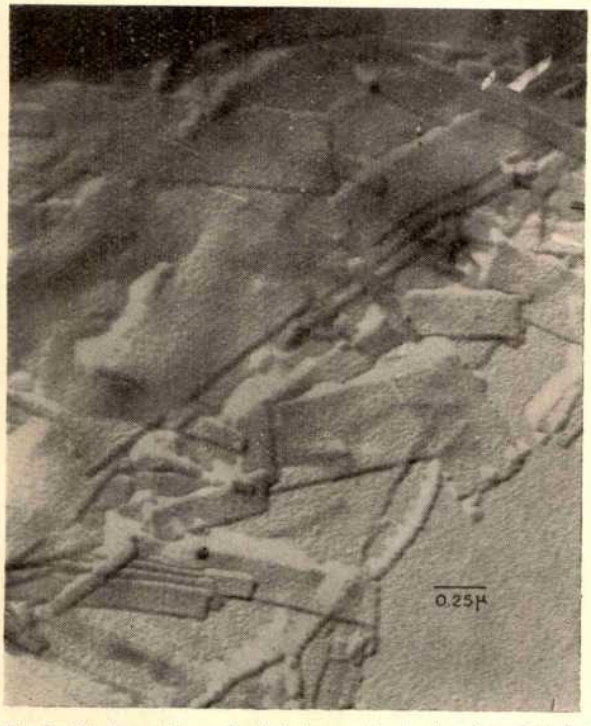

Fig. 3. Electron micrograph of single crystals at edge of quadrite for polypropylene sample isothermally crystallized in 0·01 per cent solution of α-chloronaphthalene at 115° C

interwoven, lath-like lamellar crystals are visible. Similar crystals are clearly delineated in the higher magnification electron micrograph of Fig. 2, which represents another portion of the fracture surface. The rectangular crystals appear to be about 3–8μ in length, 0·2–0·5μ in width, and about 125–150 Å in thickness. They are remarkably similar to the crystals which have been recently obtained[6] from dilute solution crystallization of isotactic polypropylene in α-chloronaphthalene (αCN). This is seen from Fig. 3, which shows a group of lamellar single crystals found at the edge of a quadrite on isothermal crystallization at 115° C of a 0·01 per cent solution of polypropylene in αCN. Note the marked morphological similarity of these crystals with those of Figs. 1 and 2. Also, in both the bulk sample as well as the dilute solution sample, the lamellar surfaces are smooth, the edges are well defined, and there are no indications of spiral growth.

The bulk sample crystallized at high pressures was also examined by X-ray diffraction and by differential thermal analysis. These data indicate that the sample had crystallized in the γ-modification of polypropylene[7]. The sample prepared by dilute-solution crystallization is known, however, to be in the α-modification[6]. Thus, despite the common morphology of the crystals of the bulk sample and the crystals of the dilute-solution crystallized sample, the crystal structure is triclinic in the first instance and monoclinic in the second.

These results show that crystallization in the form of lath-like lamellar crystals can occur both for the α-form and the γ-form of isotactic polypropylene. Also the marked similarities in morphology of the bulk-crystallized and the dilute-solution crystallized samples strongly suggest that the chain molecules in the bulk sample are folded and that restricted chain folding, as already noted for the α-form crystals[6], probably also occurs in the γ-form. Examination of the suggested unit cells of the two different crystal structures shows they are closely related. It would seem that one could be converted to the other by partial slip along fold planes. Turner Jones *et al.*[7] have, in fact, shown that the γ-form is converted to the α-form by mechanical deformation, while Kardos *et al.*[8] have shown that the γ-form can be converted to the α-form by thermal treatment.

Structure Studies on Ternary Vanadium–Molybdenum Oxides

A BRIEF report on the crystal structures of some of the phases observed in the ternary vanadium–molybdenum–oxygen system[1] is presented below.

A phase of the composition $VMoO_5$, which has been reported recently[2], has been found to have a tetragonal unit cell with the dimensions $a = 6{\cdot}6078$ Å, $c = 4{\cdot}2646$ Å, and the space group $P4/n$. A single crystal study, including least squares refinement of atomic parameters to an R-value of 0·054, has revealed that the structure is isotypic with that of $MoOPO_4$ (ref. 3). The vanadium and molybdenum in $VMoO_5$ are structurally equivalent with the molybdenum and phosphorus, respectively, in $MoOPO_4$ and, accordingly, the formula of the compound may be written $VOMoO_4$. The structure is built up of strings of distorted VO_6 octahedra running parallel to the c axis. These strings are mutually connected by quite regular MoO_4 tetrahedra. The vanadium–oxygen distances within the octahedra are 1·68, 2·59, 1·97 (4x) Å, and the four molybdenum–oxygen bonds are 1·76 Å.

Another phase of the approximate composition V_2MoO_8 has been reported by Magnéli and Blomberg[4]. In this study, the powder pattern of this phase was indexed on

the basis of a monoclinic unit cell with the dimensions $a = 19{\cdot}32$, $b = 3{\cdot}621$, $c = 4{\cdot}107$ Å, $\beta = 90{\cdot}3°$, which is in close agreement with the values published recently by Freundlich and Pailleret[5]. Weissenberg photographs of several crystals invariably showed the presence of twinning with (001) being the twin plane. The single crystal studies revealed also that the true b axis is doubled, the layer lines with k odd (crystal rotated around [010]) showing only continuous streaks along the bows parallel to a^*. This behaviour indicates one-dimensional disorder—a kind of stacking fault—which can be explained readily in terms of the structure details.

The structure of the cell corresponding to the lattice parameters listed above, the stacking lattice[6], has been determined and refined to $R = 0{\cdot}065$. The structure, a distorted variant of the Nb_3O_7F-type[7] with vanadium and molybdenum statistically distributed over the two metal atom positions, exhibits $C2$ space group symmetry. The oxygen atoms are co-ordinated (octahedrally) around the metal atoms with two short, three intermediate, and one long molybdenum–oxygen bond. Distortion towards five-co-ordination is thus appreciable. The co-ordination can be considered intermediate between that in vanadium pentoxide and molybdenum trioxide.

Molybdenum may replace vanadium in the V_2O_5 structure to a considerable extent, thus forming a range of solid solution $(Mo_x,V_{1-x})O_{2\cdot5}$, where $x_{max} \approx 0{\cdot}30$[1]. This finding differs slightly from the results of Magnéli and Blomberg[4], who reported a solid solution of molybdenum trioxide in V_2O_5 vanadium pentoxide. Over the solid solution range, unit cell dimensions change continuously from the values $a = 11{\cdot}514$, $b = 3{\cdot}562$, $c = 4{\cdot}371$ Å for vanadium pentoxide to $a = 11{\cdot}809$, $b = 3{\cdot}650$, $c = 4{\cdot}174$ Å for the composition $Mo_{0\cdot30}V_{0\cdot70}O_{2\cdot50}$. Single crystal photographs reveal that the symmetry of the molybdenum-rich phase is, in fact, monoclinic with $\beta = 90°$ and that the systematic extinctions are consistent with space groups $C2/m$, Cm, and $C2$. The symmetry has thus changed from orthorhombic to monoclinic somewhere in the solubility range ($0 < x < 0{\cdot}30$). Powder data obtained for the composition $x = 0{\cdot}30$ are in general agreement with the d values listed by Freundlich and Pailleret[5] for "$MoV_2O_{7\cdot5}$". The compound $Mo_4V_6O_{25}$ reported by Munch and Pierron[8] may also be identical with this phase.

Andersson has shown[7] that the structure of Nb_3O_7F can be regarded as the second member ($n = 3$) of a homologous series, M_nO_{3n-1}, in which the first possible member ($n = 2$) corresponds to the ideal V_2O_5 structure. Thus, there is a close relationship between the structure of V_2MoO_8 and V_2O_5, even though they are distorted in different ways from the ideal regular octahedral arrangements. But when molybdenum is substituted for vanadium in V_2O_5 the observed symmetry changes indicate that the structure gradually adopts the distortion exhibited in V_2MoO_8.

Orientation-induced Nucleation in Polymer Crystallization

IT is a well-known fact that the crystallization kinetics of polymers crystallizing from the melt are influenced by the mechanical history of the sample[1,2]. Strain-free samples show a larger crystallization half-time than samples in which the strain has not been completely removed by relaxation at a suitable temperature[3,4]. A larger number of nuclei has been assumed to be present in strained samples than in strain-free ones. This has been called "orientation-induced" or "stress-induced" nucleation.

This communication presents a morphological description of the phenomenon and of the underlying type of nucleation. My observations were made with a microscope (Reichert 'Zetopan-Pol') equipped with a hot stage and 24-mm camera, and mainly with the polarizers crossed. For most of my experiments I used polypropylene, but similar phenomena were also observed with several other polymers.

Polypropylene, when melted at 250° C and cooled to 140° C, crystallized slowly at this temperature, and only a few spherulites were formed. Application of a small shear stress (about 0·1 kg/cm²), however, resulted in abundant nucleation of small spherulites in long rows parallel to the direction of shear.

Heavy strains could also be introduced when the polymer was milled at 180° C on a two-roller mill and later quenched. A microscopic specimen was made at 200° C from a piece of about 2 mg weight cut from the quenched milling sheet. When the specimen was allowed to cool slowly, sharp birefringent lines developed, which gradually increased in number and birefringence (Fig. 1). Sometimes these lines were visible above the normal melting point of the polymer (172° C). The sign of the birefringence indicated that the polymer chains were

Fig. 1. Nucleation lines in a polypropylene melt at successive stages of cooling. (×*c.* 135)

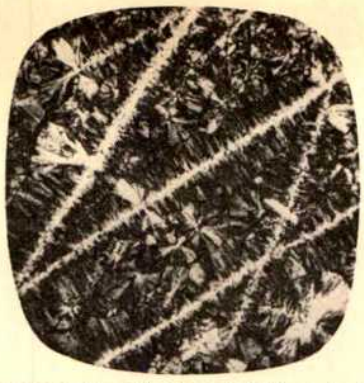

Fig. 2. "Spherulitic" outgrowth after orientation-induced nucleation. (×c. 135)

parallel to these lines. Where the density of these lines was low—namely, in a polymer sample made at small shear stress—normal fibrillar outgrowths could be seen and these proved to be similar to those of the spherulites (Fig. 2). I have called these lines "nucleation lines", and the type of nucleation "orientation-induced nucleation" although the latter is not a new term.

Provided the temperature was kept below 210° C, the phenomenon observed in Fig. 1 could be repeated at will by heating and cooling—the nucleation lines invariably appearing in the same place. After heating above 210° C the density of the nucleation lines observed on cooling decreased. When I heated my sample (intrinsic viscosity$_{\text{dec. }135^\circ\text{C}}$ = 3·1) at 240° C for 1 min, the lines completely disappeared (see ref. 4, Fig. 2). For a material of higher intrinsic viscosity a higher temperature was necessary in order to bring about the complete disappearance of the orientation-induced nucleation.

Unlike stretched rubbers, sheared polypropylene does not crystallize as a whole above its normal melting point; this is probably because the ratio of viscosity to elasticity of the molten polymer is not sufficiently high to maintain a recoverable strain sufficient for crystallization. On the other hand, at the locus of the nucleation lines the melting point of the polymer has probably increased considerably owing to a certain degree of alignment of polymer chains in the melt. A peculiar feature is that the strain is not homogeneous but culminates in lines.

Because a normal fibrillar outgrowth was found to be typical of lamellar crystallization in bulk polymers, the phenomenon of the nucleation lines and the subsequent growth bears a close relationship to the morphology found in crystallized stretched rubber[5] and even in the crystallization of a stirred polymer solution[6], where long strands of short lamellae were found, connected by a central string.

Electron Spin Resonance of Nickel in Synthetic Diamonds

IN addition to the ordinary nitrogen hyperfine lines in diamond[1,2], an isotropic line was observed at 77° K in certain polycrystalline samples of synthetic diamond. This line, which does not appear in natural diamond, has a g-value of 2·0310 ± 0·0005 and a width of ~6 gauss. Samples from Japan, the General Electric Company (U.S.A.) and from the Adamant Research Laboratory, South Africa, were investigated.

The ratio of the intensity of the new line relative to the intensity of the central line of the nitrogen spectrum varied from sample to sample, being the greatest (about 2·4) for the Japanese diamonds. The line width of the central line of the nitrogen spectrum in the Japanese diamonds is also about 6 G. The new line was also observed in a single crystal of synthetic diamond, and no anisotropy was observed.

In an effort to identify the line, synthetic diamonds were made containing no nickel, as most synthetic diamonds are known to contain nickel[3]. For example, diamonds were made containing cobalt and iron, and in both these cases the additional line was absent. Measurements were also made at 20° K and ~4° K, but no splitting of the line was observed.

Ludwig and Woodbury found an isotropic line in silicon[4] belonging to nickel, with a g-value of 2·026. They could explain its behaviour by assuming that the nickel was present as Ni^+ (spin $\frac{1}{2}$) in an interstitial site. The line was motionally narrowed and below ~2° K the spectrum split and several geometrically non-equivalent sites could be distinguished.

With nickel in germanium[5], they concluded that the nickel was present as Ni^- in a substitutional site. Above 20·4° K the Ni^- centres in germanium re-orient so rapidly that the anisotropic set of six lines collapses into one line.

Reaction with Propane of $I(5^2P_{1/2})$, produced by Photolysis of Iodine in the Continuum of the $B^3\Pi^+_{ou} - X\,^1\Sigma^+_g$ System, and by Collisional Release inside the Banded Region

FROM an analysis of the kinetics of the formation of i-propyl iodide in irradiated mixtures of iodine and propane, we have recently shown that electronic excitation of atomic iodine to the $5^2P_{1/2}$ state greatly enhances its chemical reactivity; in respect of hydrogen atom abstraction (activation energy ~ 5 kcal/mole) its behaviour is similar to that of atomic chlorine. The $B^3\Pi^+_{ou}$–$X^1\Sigma^+_g$ electronic transition of iodine exhibits a banded region with a convergence limit at 4995 Å, and a continuum at shorter wave-lengths[1]. Dissociation of molecular iodine in the continuum produces one atom in the $5^2P_{3/2}$ ground state and one atom with the $5^2P_{1/2}$ spin-orbit orientation corresponding to an excitation energy of 21·7 kcal/mole. The occurrence of $I(5^2P_{1/2})$ reactions has been established by a study of the inhibition caused by addition of various species which deactivate $I(5^2P_{1/2})$ to the ground state:

$$I^* + M \rightarrow I + M$$

There is a general correspondence between efficiencies measured directly by flash spectroscopy[2,3] and those determined from the isopropyl iodide inhibition. The production of $I(5^2P_{1/2})$ also occurs well inside the banded region above 4995 Å; collisional release resulting from long-range attractive interaction with any added gas, and the kinetic energy available during collision, effectively shifts the continuum threshold to longer wave-lengths.

Quantum yields were measured by focusing light from a compact-source, quartz–iodine lamp (100 W), through narrow band interference filters, into the reaction cell.

The transmitted light-intensity was measured by chemical actinometry, and the *i*-propyl iodide was determined by gas chromatography, after separation of the unreacted propane on a low-temperature still. The quantum yield is independent of the area of the cell window that is illuminated, which rules out the possibility of complications arising from reaction on the glass surfaces. Most of the kinetic measurements were made in a reaction system in which a 1,000 W quartz–iodine lamp, length 15 cm, was placed parallel to the axis of a cylindrical reaction vessel, the whole being enclosed in an aluminium reflector. A variety of filters was used to determine the dependence of the kinetics on the wave-length of the radiation.

The yield of *i*-propyl iodide is accurately proportional to the duration of exposure, and to the light intensity. At 60° C in a mixture of 0·20 mm of iodine with 100 mm of propane, the quantum yield for the formation of *i*-propyl iodide is $1{\cdot}5 \times 10^{-4}$ at 4835 Å. Inside the banded region at 5020 Å, the quantum yield is $0{\cdot}7 \pm 0{\cdot}1$ of the yield at 4835 Å. The yield falls off above 5200 Å, and is very small at 5480 Å, where ground state atoms are still produced[4].

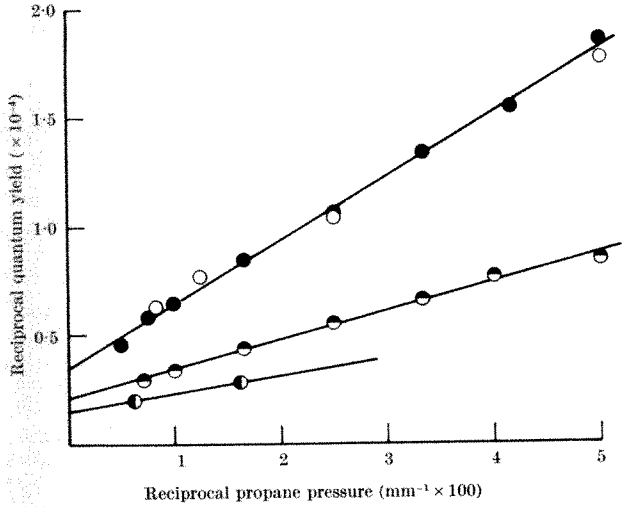

Fig. 1. Linear relationship between reciprocal quantum yield and reciprocal pressure of propane. Continuum: ●, 0·2 mm iodine + propane (30° C); ◐, 0·20 mm iodine + propane (90° C); ◓, 0·20 mm iodine + propane (60° C). Banded region, 0·20 mm iodine + propane + nitrogen (30° C) (○)

Fig. 1 shows the linear relationship between reciprocal quantum yield and reciprocal pressure of propane. The quantum yield for the banded region refers to 5020 Å, and has been divided by 0·7 to illustrate the invariance of the slope to intercept ratio with wave-length. In the latter experiments, nitrogen was added to a total pressure of 500 mm, to avoid any significant changes in pressure broadening. For a particular temperature, the ratio of slope to intercept is the same on either side of the 4995 Å threshold, and there can be no doubt that essentially the same reaction occurs in the two wave-length regions. Assuming the scheme:

$$\begin{gathered} I_2 + h\nu \rightarrow I + I^* \\ (\text{or } I_2 + h\nu \rightarrow I_2^*,\ I_2^* + M \rightarrow MI + I^*) \\ I^* + C_3H_8 \rightarrow HI + i\text{-}C_3H_7 \\ I^* + M \rightarrow I + M \\ i\text{-}C_3H_7 + I_2 \rightarrow i\text{-}C_3H_7I + I \end{gathered}$$

the rate coefficients for deactivation of $I(5^2P_{1/2})$ relative to propane may be derived from plots similar to those of Fig. 1; in Table 1 these are compared with rate coefficients measured by flash spectroscopy. We consider that as the general pattern of deactivation efficiencies is the same, the occurrence of hydrogen atom abstraction by $I(5^2P_{1/2})$ is established from these measurements.

Table 1

	H_2	I_2	CO_2	Ar	N_2
Donovan and Husain (~20° C)	1·5	88	0·0023	v-small	0·0035
This work (30° C)	0·55 ± 0·02	430 ± 10	< 0·03	< 0·05	< 0·03

Filseth and Willard[5] have reported the formation of *n*-propyl and *i*-propyl iodide in equal yield from the same reaction, and have derived a different mechanism. In our investigation, the ratio of *i*-propyl to *n*-propyl iodide was always 40 : 1, except for the first few experiments in freshly cleaned vessels, when significant amounts of *n*-propyl iodide seem to be produced by heterogeneous reaction.

Bond Character in Germanium Selenides by X-ray Spectroscopy

X-RAY spectroscopy provides a direct and powerful method of studying the electronic structure of solids[1]. It has been applied so far mainly in the investigations of energy band structure of solids[2–4] (mostly metals and alloys) and in the study of complexes[5–7]. This communication, which reports our work on the *K* absorption spectra of selenium and germanium in GeSe and $GeSe_2$, shows that this method can also be useful in determining the nature of chemical bonding in intermetallic compounds which are of special interest because of their semiconducting properties.

The absorption spectra were recorded photographically using a bent crystal X-ray spectrograph 40 cm in diameter. The experimental technique has already been described[8,9]. The intermetallic compounds were prepared in stoichiometric ratio by suitable heating and annealing. Table 1 gives the wave-lengths and corresponding energies of the germanium *K* absorption discontinuity in pure metal and in the two compounds. Table 2 gives similar data for the selenium discontinuity.

Table 1. DATA ON GERMANIUM *K* ABSORPTION DISCONTINUITY

Absorber	λ in X.U.	ν/R	Energy (*E*) eV	Δ*E* eV
Ge metal	1114·35 ± 0·05	817·7	11101·1 ± 0·4	
GeSe	1114·50 ± 0·05	817·5	11099·6 ± 0·4	−1·5 (ΔE_1)
$GeSe_2$	1114·32 ± 0·05	817·8	11101·4 ± 0·4	− − − ($\Delta E'_1$)

Table 2. DATA ON SELENIUM *K* ABSORPTION DISCONTINUITY

Absorber	λ in X.U.	ν/R	Energy (*E*) eV	Δ*E*
Se metal	977·82 ± 0·07	931·94	12651·1 ± 0·5	
GeSe	977·60 ± 0·07	932·14	12653·8 ± 0·5	2·7 (ΔE_2)
$GeSe_2$	978·02 ± 0·07	931·75	12648·5 ± 0·5	−2·6 ($\Delta E'_2$)

It is generally believed that the inflexion point on an X-ray absorption edge represents the top of the outermost filled band. For germanium and selenium it can be taken to represent the top of the valence bands which consist, respectively, of $4p^2$ and $4p^4$ electrons. In GeSe some of the $4p^2$ electrons of germanium are transferred into the conduction band of selenium because of the higher electronegativity[10] of the latter (2·4 for selenium and 1·8 for germanium). This results in the lowering of the energy of the germanium edge in the compound giving the shift ΔE_1. However, in the band structure of selenium the bonding and the non-bonding $4p$ bands are

completely occupied[11] and the germanium electrons can only go into the antibonding $4p$ band, which in pure selenium is at 1·8 eV from the valence band[12]. We obtain, therefore, in the opposite direction, a considerably higher shift ΔE_2 for the selenium K edge. On the assumption that the distribution of the transferred electrons remains more or less of the same type in the compound, E_g for GeSe is $(2{\cdot}7-1{\cdot}5)=1{\cdot}2$ eV. This is in good agreement with the value 1·0 eV obtained by Asanabe and Okazaki[13] when they used the normal resistivity variation method. The electron transfer in GeSe shows that the bonding in this compound is largely of the ionic type. The NaCl type structure[14] of this compound further supports this contention.

However, the situation in $GeSe_2$ would seem to be entirely different. The germanium edge in this compound remains practically at the same position while the selenium edge is shifted towards lower energies by 2·6 eV. The change in energy of the selenium edge most probably indicates strong covalent bonding in this compound, which lowers the energy of the top of the selenium valence band. It would seem that the lone germanium atom in $GeSe_2$ is unable to satisfy the electronegativity requirements of two selenium atoms and thus this compound 'prefers' covalent linkage.

We thank Dr. K. P. Sinha of the National Chemical Laboratory, Poona, for helpful discussions and the Directorate of Industries, Government of Maharashtra, Bombay, for financing the research scheme under which a part of this work has been done. S-Demethylation catalysed by the Formation of Metal Complexes

S-ALKYLATION has been observed to occur *in situ* when certain metal complexes of β-mercaptoethylamine and other thiols are treated with alkyl halides in dimethylformamide solution[1]. We have observed *S*-demethylation reactions with certain metal chelates of thioethers.

8-Methylthioquinoline (N-SMe) forms complexes with several transition metal ions in which it functions as a neutral bidentate chelate group[2]. However, it reacts with sodium tetrachloroaurate (III) in acetone solution to yield yellowish-green crystals of dichloro-8-quinolinethiologold (III), $Au(N\text{-}S)Cl_2$ (I), which is a non-electrolyte in nitrobenzene and nitromethane. The infra-red and nuclear magnetic resonance spectra of (I) show no peaks that can be attributed to a methyl group. The compound (I) was also prepared from 8-quinolinethiol and sodium tetrachloroaurate (III).

If solutions of $M(N\text{-}SMe)Br_2$ (M = palladium or platinum) in dimethylformamide are heated for 10 h and alcohol is then added, the thiolo-bridged complexes $M_2(N\text{-}S)_2Br_2$ separate when the solution cools. Similarly, when solutions of $Pd(As\text{-}SMe)X_2$ (As-SMe = dimethyl-*o*-methylthiophenylarsine[3]; X = chlorine or bromine) in dimethylformamide are heated, the thiolo-bridged complexes $Pd_2(As\text{-}S)_2X_2$ can be obtained. Similar metal-ion catalysed dealkylation reactions of ether groups have recently been reported to occur with copper (II) complexes of certain Schiff bases[4].

It is possible that these thioethers could, in the presence of metal ions, effect transmethylation analogous to what has been observed with *S*-adenosylmethionine in living systems[5,6].

Rapid Voltammetric Determination of Methionine with a Platinum Electrode

THE presence and concentration of methionine in aqueous media can be quickly determined by a simple voltammetric method. The solution for electrolysis must be acidic and must contain a moderate amount of chloride ion. Using a platinum microelectrode as the working anode and a saturated calomel electrode (SCE) as the cathode, anodic current–voltage curves with limiting currents proportional to the methionine concentration are obtained. The voltammetric waves are well developed between +0·7 and +1·0 V against the SCE.

The usual voltammetric technique was used. Electrolysis was carried out at 25° C in an H-shaped cell. Solutions of methionine were made in distilled water to which had been added known amounts of hydrochloric acid and sodium chloride. The methionine was a Dow product of 99·9 per cent purity. For methionine concentrations smaller than 100 p.p.m., a platinum microelectrode about 3 mm long and 0·6 mm in diameter was used as the working anode. The platinum wire was sealed into the end of a glass tube containing some mercury for electrical contact, as usual. For concentrations greater than 100 p.p.m. a much smaller electrode was used. This was made from the same platinum wire; after sealing, the wire was cut and filed flush with the glass surface. Current–voltage curves were automatically recorded with a Sargent 'Model XV' polarograph. The voltage was applied at a rate of 0·05 V/min.

The anodic wave obtained under the experimental electrolysis conditions is believed to involve the thio group of the methionine molecule. Micro-scale complete electrolysis indicated a two-electron oxidation step. Because the electrolysis products have not yet been identified, no plausible electrode reaction mechanism can be proposed. In Fig. 1 the waves develop between +0·7 and +1·0 V. In order for such waves to appear, the solution must be acidic and must also contain a moderate amount of chloride ion. Apparently both the hydrogen and chloride ionic species are necessary for the wave to develop in good form. Concentrations of hydrogen and chloride ions can be widely varied with practically no change in

either the half-wave potential or the limiting current (Fig. 2). For methionine concentrations of 1–500 p.p.m., the best waves are obtained with 1–2 M solutions in chloride, provided the solutions are definitely acidic (pH ~2 or less).

In neutral solutions very poor waves may appear; in basic solutions there is no evidence of a wave at all. This is shown in Fig. 3. Methionine solutions acidified with sulphuric acid, and containing no chloride, produce waves at a more anodic potential than that required in the presence of chloride ion. The form and reproducibility of these waves are not satisfactory for analytical work.

In Fig. 1 the limiting currents are proportional to methionine concentration. They are reproducible to within ± 5 per cent for concentration levels of 5–500 p.p.m.

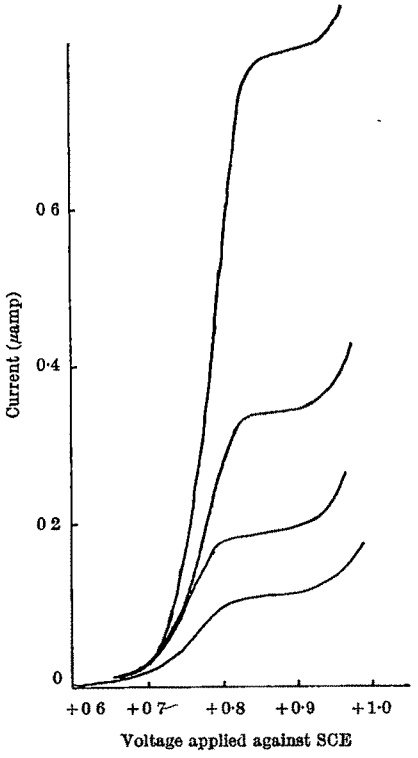

Fig. 1. Current–voltage curves of methionine, showing proportionality of current to concentration of methionine. Curves obtained with the smaller electrode. Chloride concentration, 1 M; hydrogen ion concentration, 0·1 M. The curves represent concentrations of methionine of 50, 100, 200 and 500 p.p.m.

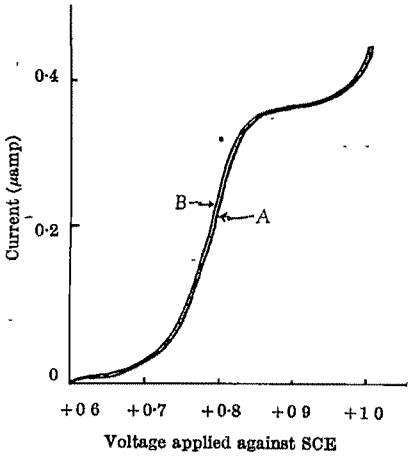

Fig. 2. Current–voltage curves of methionine (200 p.p.m.) with different chloride and hydrogen ion concentrations. Curve *A*: chloride, 1 M; hydrogen, 0·1 M; curve *B*; chloride, 2 M; hydrogen, 0·3 M

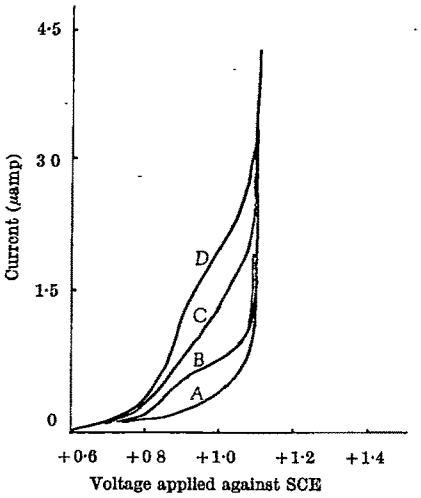

Fig. 3. Current–voltage curves of methionine in neutral solution. Methionine concentration *A*, 0 p.p.m; *B*, 50 p.p.m.; *C*, 100 p.p.m.; *D*, 150 p.p.m.; sodium chloride concentration, 1 M. Curves obtained with the larger electrode. In basic solutions a curve like *A* is obtained, irrespective of methionine concentration

The waves start to form ahead of the chloride wave such as to suggest the possibility of a methionine-electrode complex; this complex can apparently be electro-oxidized at a less positive potential than the chloride, thus making possible development of a wave before discharge of chloride ion. If iodide or bromide ions are present instead of chloride, no waves appear; a slight shift in the decomposition potential of these ions to less positive values occurs, which probably indicates depolarization of the halide ions by methionine. It is probable that methionine–electrode complexes with iodide or bromide also form, but these complexes may decompose so near to the decomposition potential of the halide ions that distinct methionine waves cannot develop.

Regarding the platinum electrode, the occasional difficulties arising from oxidation of the electrode in chloride media[1], and the maxima that may form with stationary electrodes[2], should be considered. Sometimes the platinum electrode behaved very erratically, especially when the applied potential exceeded +1·1 V. In such cases the electrode was made the cathode at −1·9 V for a few minutes while it was dipped into the solution to be electrolysed; the potential was then reduced to −0·6 V and the polarity was reversed; after a waiting period of about 10 min, current–voltage curves were obtained. The use of two electrodes, a smaller one for methionine concentrations greater than 100 p.p.m. and a larger one for smaller concentrations, practically eliminated the undesirable formation of maxima. Although a stationary platinum micro-electrode requires a few minutes to give a steady current with successive increments of applied potential, satisfactory reproducibility of the waves was attained by applying the potential continuously at a rate of 0·05 V/min (ref. 3). There was no particular advantage in manually obtaining point-by-point current–voltage curves. When the electrode was rotated at rates of 200–1,000 r.p.m., very steep current plateaux were produced.

Determination of methionine in various hydrolysates was made either from standard calibration curves or by the standard addition method. In the analysis of unknown samples possible interferences should be considered. Organic sulphides are likely to produce anodic waves at the same potential. For example, the hydroxy analogue of methionine yields identical waves with those of methionine. Bromide ion definitely interferes. Advantage can be taken of the fact that most organic sulphides are more or less soluble in ethyl ether (methionine is not) and can be easily removed by extraction with the ether.

The merit of the present method lies in its simplicity and rapidity. Like most voltammetric methods, it can be used satisfactorily with relatively small sample volumes; if necessary, only 0·1 ml. of sample solution can be used. The sample is not destroyed—an advantage which is not obtained with most of the chemical methods used for methionine analysis.

I thank Edgar Elkins and Dr. Dalton MacWilliams for their interest and useful discussions during this work.

Evaporation Reduction of Water

SINCE Langmuir explained the nature of monomolecular films, efforts have been made to use them as economically feasible reductants of evaporation of water. Apart from practical engineering difficulties in encountering breakage of the film due to winds, dirt deposits, etc., there are two built-in difficulties: (1) Reduction of evaporation causes a warming up of the water which corresponds to an increase of the vapour pressure. Thus the advantage of evaporation reduction is lost at the slightest break of the film[1]. (2) Fatty alcohols used to obtain the monolayer are attacked by bacteria, namely *Pseudomonas* and *Flavobacterium*[2].

I found that spreading solid paraffin to which a white reflective pigment has been incorporated on the surface of water overcomes these difficulties, as paraffin is biologically inert and the incorporated pigment reflects direct sunlight.

Paraffin without pigment is an excellent barrier against liquid water and water vapour. Its refractive index, however, is too near that of water and therefore does not sufficiently reflect direct sunlight.

Table 1 shows how the temperature rises as a result of efficient reduction of evaporation. The experiments were carried out in class "*A*" pans on the roof of the Water Planning Authority building in Tel-Aviv.

Table 1

Substance	Daily evaporation (mm)	Evaporation compared with untreated water (per cent)	Surface temperature (° C)
Nil	2·1	100	20
White polystyrene balloons	1·32	63	18
Limna	1·86	88·5	19
Magnesium stearate powder (87 g/m²)	1·37	65·0	17
Zinc stearate (91 g/m²)	1·44	68·5	18
Polyurethane foam covering 85 per cent of the water surface	1·17	55 7	19
Paraffin powder (150 g/m²)	0 17	8 1	21 5

A second experiment was carried out with paraffin containing 10 per cent (by weight) of titanium dioxide and 20 per cent (by weight) of calcium carbonate (precipitated). The temperature measured 1 cm below the surface was lower than the temperature of the untreated water (20° C and 19° C) and the saving in evaporation was 33 per cent, for paraffin treated with titanium dioxide, and 35 per cent, for paraffin treated with calcium carbonate.

The pigment containing paraffin was prepared as follows: 450 g paraffin (melting range 58° C–60° C) was melted at about 90° C and 50 g titanium dioxide added with constant stirring. After resolidification of the titanium dioxide-containing paraffin it was milled (under cooling with liquid air) and the powder passed a sieve of 40 mesh. 55 g/m² were broadcast.

The same technique was used for the incorporation of a number of pigments like calcium carbonate, zinc oxide, barium sulphate, etc. For obvious reasons (lightness, physiological inertness, etc.) calcium carbonate is best.

Results similar to the ones with pigmented paraffin were obtained with white polypropylene powder and with white high-density (Ziegler) polyethylene powder.

However, the synthetic plastic materials were not exposed for a long enough time for any degradation due to the combined effect of ultra-violet rays and water vapour to become apparent. The degradation is first signalled by a yellowish–brownish tinge, and defeats the reflective power of the undegraded white material.

Fox[3] recently reported similar results using an oil-wax surfactant system. Unfortunately he did not report the temperature readings.

Interference with the Determination of Aldrin and Benzene Hexachloride Residues by Gas Chromatography

WE wish to report an artefact which has occurred in our laboratory during the analysis of plant materials for residues of organochlorine pesticides by gas–liquid chromatography, with the electron capture detector. It occurs as a peak in a position very close to that of aldrin, when using a silicone elastomer on 'Celite' packed column, and at the same position as β-benzene hexachloride (BHC), when using an 'Apiezon *L*' on 'Celite' packed column.

Solvents, as purchased, often give this peak, but the contaminant causing the peak can be removed by distillation through a short fractionating column. Distilled solvents and water are recontaminated if kept in contact with polythene, for example, storage bottles and pipework. The contaminant can be extracted, by redistilled hexane, from absorbants such as 'Florisil', alumina and cellulose powder; and from clean glassware, glass-wool, cotton-wool and filter papers, especially after these have been in our laboratory for a few days. It was recovered in relatively large quantities from hexane swabbings of cupboard-door windows and from a hexane-extract of laboratory dust.

Column chromatography on alumina of a hexane-extract of several grams of laboratory dust, using gas–liquid chromatography with electron capture detector to monitor the eluate, gave a yellow oily fraction producing only the artefact peak. The infra-red spectrum of this fraction suggested a phthalate ester.

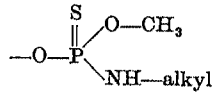
Di-*n*-butyl phthalate has the same retention characteristics as the contaminant and is strongly electron capturing—a solution of 1×10^{-6} g/ml. giving about the same response as a solution of 2×10^{-8} g/ml. of aldrin.

We have been unable to determine the source of the contaminant in solvents delivered in steel drums, or in glass bottles with loose aluminium foil disks separating the polythene cap-insert from the bottle contents. We believe that the main source of the contamination in the laboratory is the polyvinyl acetate-based paint, containing dibutyl phthalate as plasticizer, which was used to paint the walls and ceilings. Polyvinyl acetate latex-based adhesive is often used to secure aluminium foil coverings to cardboard inserts in bottle caps, and the adhesive on tapes

used to seal capped bottles often contains dibutyl phthalate; these are possible sources of the contaminant found in absorbants from newly opened bottles. This contamination is so widespread in our laboratory and, even with the most stringent hygiene, so difficult to control that care must always be taken when identifying a peak with β-BHC or aldrin, especially when the residue level is too low to confirm the identity by some other technique, such as thin-layer chromatography.

β-BHC is unlikely to occur as a residue in crops because its concentration in the mixed-isomer of BHC is very low and is virtually zero in the insecticide γ-BHC (lindane). Therefore, a peak, tentatively identified as β-BHC, when using 'Apiezon *L*' columns, can usually be regarded with suspicion.

The amount of the contaminant varies unpredictably and makes the quantitative determination of aldrin in crops virtually impossible by the silicone column method. Because the contaminant peak tails into the aldrin peak position, quantitative aldrin determinations are also difficult using the 'Apiezon *L*' column when the contaminant peak is greater in height than the aldrin peak.



We thank Dr. N. T. Crosby, of the Laboratory of the Government Chemist, for running and interpreting the infra-red spectrum.

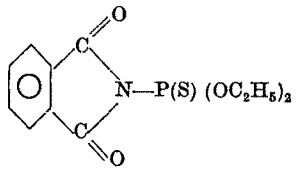
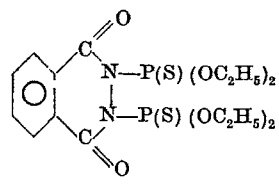
Biological Activity of Phosphoramidothionates

IN the course of our work on this class of compound an animal-anthelmintic[1] and a selective herbicide[2] had previously been discovered. Common to the structures of the two compounds was the linking of the phosphoramidothionate group (I) to a chlorinated phenyl ring by an oxygen atom. Our speculations on biological activity led us to replace this atom by nitrogen and to investigate the effects of a different type of toxophoric phosphoramidothionate group (II):

(I)



(II)

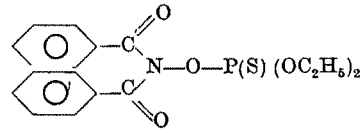


We were particularly interested in the biological effects resulting from an incorporation of the moiety,

$$-C(O)NP(S)(OC_2H_5)_2,$$

into heterocyclic structures. These we were able to synthesize when the inherent nucleophilicity of certain amide-type phosphorothionate esters first revealed itself in our own investigations, before 1960[3,4]. Among the new types of structure that thus became available were (III) and (IV).

(III)



(IV)

It was known that certain compounds containing the groups, $-CH_2\ O/S-$ and $-C_2H_4\ O/S-$, between N and P in (III) were insecticidal. Quite unexpectedly, we found (III) to be an excellent fungicide, controlling powdery mildew completely at concentrations of about 10 p.p.m. Because (III) was the first organic phosphorothionate to be highly fungicidal and as it contained a peracylated nitrogen atom at phosphorus, its mammalian toxicity became of practical as well as of theoretical interest. This toxicity was found to be uniquely low for a phosphorothionate pesticide—much lower than the toxicity of any other heterocyclic phosphorus derivatives reported[5]. Compound (III) proved to be a very weak esterase inhibitor and had the following acute, oral toxicity in mg/kg body-weight.

Animal:	Rats		Cavies	Chicks
Sex:	Male	Female	Male	Male
$L.D._{50}$	5,660	4,930	5,660	~4,500

The actual causes of this remarkable biological behaviour of (III) have not yet been experimentally established. They may involve the well-known fact that five-membered imide rings are readily opened by the action of basic reagents, and the fact that in phosphorus pesticides a carboxyamido group is more readily hydrolysed than the phosphorothionate group[6]. Thus, the metabolic fate of (III) may primarily arise from interaction with amidases instead of esterases. Also, there may be a distinct difference in the reaction rates involving the rupture of the carbon–nitrogen bonds and the phosphorus–nitrogen bond. The rate of attack on the trigonal, electron-deficient carbonyl-carbon of the planar phthalimide group should be relatively high. The rate of 'backside' attack on the less electron-deficient, tetrahedral phosphorus-atom may be decreased by steric interference of the phthalimide substituent. Reduction of this interference by insertion of an oxygen atom between nitrogen and phosphorus should lead to easily detectable, cholinergic activity. This conjecture is supported by the acute, oral toxicity of the insecticide, Bayer 22408 (V), on rats ($L.D._{50}$, 500 mg/kg). On the molecular $L.D._{50}$ basis, (V) is fourteen times as toxic to rats as is (III).

(V)

For a more complete description of our new fungicide, 0,0-diethyl phthalimidophosphonothionate (III), the following details should be mentioned. The compound consists of white, flat crystals that melt at 83°–84° C; it has a boiling point of 99°–101° at 7×10^{-4} mm and shows the following solubility (in moles per 100 moles of solvent at room temperature):

C_6H_6	CCl_4	$CH_3COOC_2H_5$	C_2H_5OH	S	*n* C_6H_{14}	H_2O
33·8	25	23 3	1 1	0·74	0 38	< 0 01

The symmetrical structure of (III) has also been confirmed by proton magnetic resonance. The phosphorus-31-chemical shift relative to 85 per cent phosphoric acid has a value of −56·6 p.p.m. The infra-red absorption spectrum shows the following intensities:

cm^{-1}	1,785	1,740	1,715	1,370	1,300–1,285	1,065–1,025	971
intensity	m	s	s	m	vs	vs	m

Interestingly, the compound does not undergo the thiono-thiol isomerization characteristic of compounds containing the group, $>P(S)(OC_2H_5)$. This stability evidently exists with all compounds which contain the moiety, phthalimido-$P(S)(OC_2H_5)$, but we do not know

of any other phosphoramidothionate alkyl esters possessing the same kind of stability. A preparation method for compound (III) has been published elsewhere[7].

Fungicidal activity and mammalian toxicity were investigated by D. R. Mussell and K. J. Olson, respectively. Nuclear magnetic resonance was investigated by E. B. Baker and J. P. Heeschen, and infra-red absorption by R. A. Nyquist.

An Estimate of the Hammett Reaction Constant for the Basicities of Substituted Benzophenones

HAMMETT reaction constants ρ for the basicities of several series of carbonyl compounds are known and have been found to correlate linearly with the infra-red frequencies of the carbonyl bond[1]. This constant is not available for monosubstituted benzophenones (that is, substituted in one ring only), because the basicities of only a few of them have been measured[2,3] and the data obtained give a very poor Hammett plot. A knowledge of this constant would, however, be of interest in connexion with the linear correlation with infra-red frequencies. Therefore an attempt to estimate it indirectly is reported here.

Use can be made of the known fact that groups inserted between the benzene ring and the reaction centre produce an attenuation in the transmission of substituent effects, reflected in a reduced reaction constant ρ′, the fall-off factor ($\pi = \rho'/\rho$) being independent of the reaction centre and characteristic of the bridging group only[4]. Thus, for example, the ρ′ value for the acidities of substituted trans-cinnamic acids[5] is 0·46 (when *p*K's are plotted against σ) as compared with $\rho = 1$ for substituted benzoic acids, giving a fall-off factor of 0·46 for the vinylene group. The reaction constant for the basicities of substituted trans-chalcones[6] must be similarly reduced relative to the value for substituted benzophenones. The acidity constants of protonated substituted chalcones (pK_{BH^+}) correlate well with the σ^+ substituent constants[6], giving a ρ^+ value of 1·60 (in obtaining this value the *p*K's were corrected to the acidity function scale of Jorgenson and Hartter[7]). Using the fall-off factor of 0·46, this leads to $\rho^+ = 3{\cdot}5$ for the acidities of protonated benzophenones. This is fairly close to the value that can be obtained from the data[3] on the basicities of benzophenone and its *p*-chloro-derivative (~4·3), but is much higher than the value that may be obtained from the data[2] on the basicities of benzophenone and its *p*-methyl-derivative (~1). It is also higher than the value (~2) guessed by Yates and Scott[8]. It is remarkable that this indirectly estimated ρ^+ falls excellently on the linear plot of the ρ^+ values for the acidities of other protonated carbonyl compounds against infra-red frequencies of the carbonyl bond[9], as shown in Fig. 1.

One might suppose that using the fall-off factor for the methylene group ($\pi = 0{\cdot}489$), obtained from the acidities of phenyl-acetic acids[4], and the ρ value for the acidities of protonated substituted benzyl phenyl ketones[2], an equally satisfactory estimate of the ρ value for the acidities of protonated benzophenones could be made. The pK_{BH^+} values of protonated benzyl phenyl ketones, also corrected to the new acidity function scale[7], correlate with the σ substituent constants giving a ρ value of 0·72.

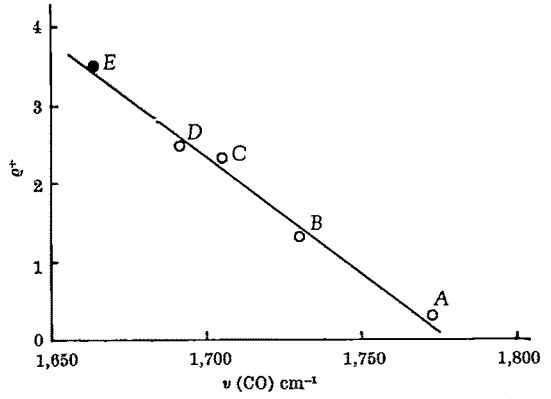

Fig. 1. Hammett reaction constants for the acidities of protonated substituted carbonyl compounds versus the carbonyl vibration frequency. *A*, Benzoyl chlorides *B*, benzoic acids; *C*, benzaldehydes; *D*, acetophenones; *A-D*, experimental values (taken from ref 1), *E*, estimated value for benzophenones (this work)

This, together with the fall-off factor for the methylene group, leads to a ρ value of only 1·43 for protonated benzophenones, which does not correlate at all well with the infra-red frequency of the carbonyl bond. The mere fact that the basicities of substituted benzyl phenyl ketones correlate with σ substituent constants, and not with σ^+, as do the basicities of other substituted carbonyl compounds with a direct link between the benzene ring and the carbonyl group, suggests that the methylene bridging group significantly alters the nature of the interaction of the substituent with the carbonyl group. It cuts out the conjugative interaction, which is transmitted effectively by the vinylene group. On these grounds the estimate of ρ for the basicities of monosubstituted benzophenones from the basicities of substituted chalcones should *a priori* be expected to be better than that from the basicities of substituted benzyl phenyl ketones.

On the Enthalpy–Entropy Relationship

THE changes in the enthalpy (ΔH^0) and the entropy (ΔS^0) for a given process are frequently calculated from the temperature-dependence of a parameter (k) that characterizes the process. k may be a rate coefficient, a partition coefficient or even a saturation concentration of a chemical species in a solvent. This calculation is usually equivalent to the determination of both ΔH^0 and ΔS^0 from the one single equation:

$$\ln k = \Delta S^0/R - \Delta H^0/RT \qquad (1)$$

so that the two quantities ΔH^0 and ΔS^0 are not *a priori* mutually independent.

This leads to difficulties when a linear correlation is found between the values of ΔH^0 and the values of ΔS^0 in a family of measurements, because such a correlation may have no theoretical significance. If, for example, in a series of measurements on similar systems the values of ln k do not vary very much, then there may be a linear correlation between the values of ΔH^0 and the values of ΔS^0. The slope of the straight line that correlates ΔH^0 and ΔS^0 in such an instance is directly related to the

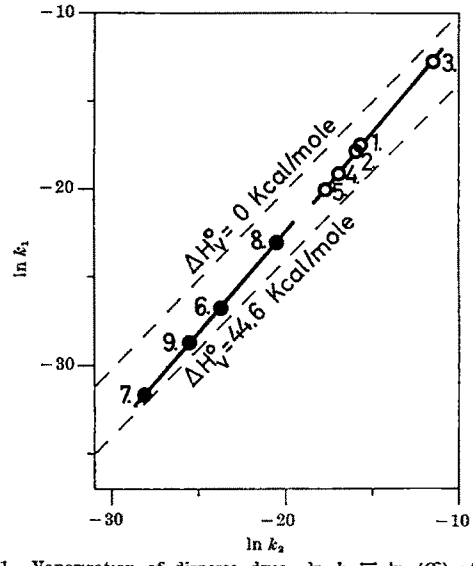

Fig. 1. Vaporization of disperse dyes. ln $k_1 \equiv$ ln (C_V) at 60° C; ln $k_2 \equiv$ ln (C_V) at 80° C. ○, Majury (ref. 3); ●, Jones *et al.* (ref. 4)

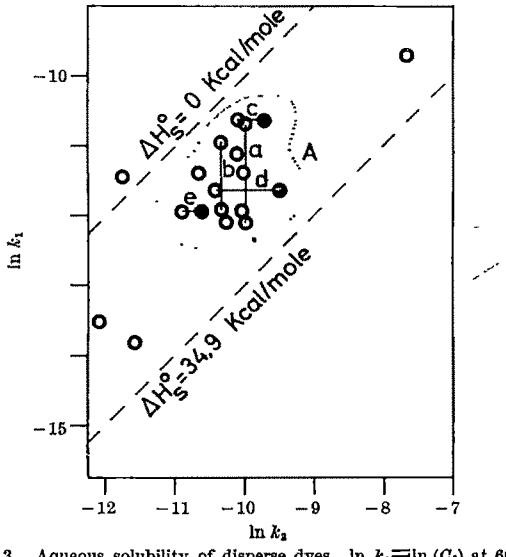

Fig. 3. Aqueous solubility of disperse dyes. ln $k_1 \equiv$ ln (C_S) at 60° C; ln $k_2 \equiv$ ln (C_S) at 80° C. ○, Patterson (ref. 5), maximum variation given by ○——○; ● Bird (ref. 6), deviation from Patterson given by ○——●. *A* denotes the "scatter area"

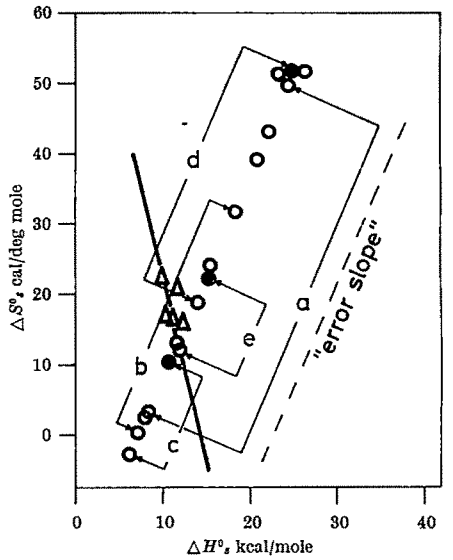

Fig. 4. Aqueous solubility of disperse dyes. The relative positions, in the new co-ordinates, of the points directly linked in Fig. 3 are indicated by the linked arrows. The correlation in Fig. 5 is here indicated by the heavy line. The broken line gives the "error slope". The symbols are as in Fig. 3, with the addition of △ (Majury) (ref 7)

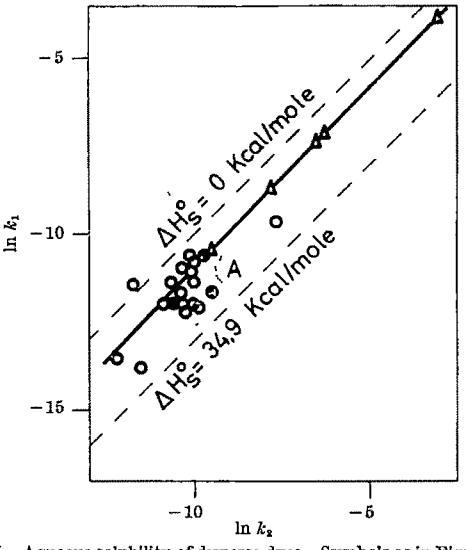

Fig. 5. Aqueous solubility of disperse dyes. Symbols as in Figs. 3 and 4. Range of ln k increased by inclusion of Majury's results (ref. 7)

mean temperature of the experiments and has been referred to as the "error slope" because this correlation may arise purely from the errors in determining ln k (refs. 1 and 2).

The problem of distinguishing the genuine from the spurious correlations between ΔH^0 and ΔS^0 is important and has been thoroughly discussed by Exner[1,2], for systems in which chemical reaction rate constants have been measured, in terms of a transformation of co-ordinates. If k_1 is the value of the parameter k when the temperature $T = T_1$, and if k_2 is the value when $T = T_2$, then a linear relationship in the co-ordinates $x^1 \equiv \Delta S^0/R$ and $y^1 \equiv \Delta H^0$ should also correspond to a linear relationship in the co-ordinates $x \equiv \log k_2$ and $y \equiv \log k_1$ (refs. 1 and 2). The problem of distinguishing the genuine correlations from the fallacious ones is therefore simplified.

In an attempt to analyse and compare the vaporization of disperse dyes with the dissolution of disperse dyes in water, we have obtained results that illustrate Exner's approach rather well, and which in addition supply measurements for a system that is completely different from the reaction-systems which he has discussed in detail[1].

Fig. 1 shows experimental results for the vaporization of disperse dyes[3,4], which have been recalculated to give the saturation vapour-phase concentrations of disperse dye (C_v, moles/l.) at 60° C and at 80° C. We have ln $k_1 \equiv$ ln (C_v) 60° C and ln $k_2 \equiv$ ln (C_v) 80° C. The linear correlations in the co-ordinates ln k_2 and ln k_1 remain as linear correlations in the co-ordinates ΔS_v° and ΔH_v° as is clear from Fig. 2. The correlation in Fig. 2 therefore appears to be genuine; in support of this the "error slope" is also given and it can be seen that it is quite different from that of the correlation lines.

In contrast to this, Fig. 3 shows some results for the saturation aqueous solubilities (C_s, moles/l.) of disperse dyes[5,6] and now ln $k_1 \equiv$ ln (C_s) 60°, while ln $k_2 \equiv$ ln (C_s) 80° C. The results form a scattered area A and the experimental uncertainty seems to be rather large. There is no clear correlation between the results in Fig. 3 in the ln k_2 and ln k_1 co-ordinates. A clear-cut correlation occurs, however, between the ΔS_s° and ΔH_s° co-ordinates. The error-lines from Fig. 3 have been transformed to Fig. 4 together with the "error slope". The "error slope" correlation in Fig. 4 is for this reason of doubtful significance.

When the range of variation of ln k is increased, however, by including aqueous solubilities measured by Majury[7], a correlation between the ln k_2 and ln k_1 co-ordinates becomes apparent, in addition to the area of scatter A (Fig. 5). In the ΔS_s° and ΔH_s° co-ordinates, the correlation in Fig. 5 is so masked by the effect of the "scatter area" A as to be difficult to detect (Fig. 4).

It would seem that these results support Exner's analysis of these problems[1]; they will be discussed in more detail elsewhere in the context of, for example, the Barclay and Butler rule[8,9].

BIOPHYSICS

Platelet Aggregation in the Variable-frequency Thromboviscometer

The importance of platelet aggregation in the initiation of thrombosis is now established, as is the variation in the quantity of these platelet masses with the conditions of flow at the site of deposition[1,2]. The morphology of an arterial thrombus consists of large amorphous masses (composed of platelet aggregates) surrounded by leucocytes and embedded in a fibrin network. A venous thrombus contains fewer platelet masses, whereas the glass tube clot has no visible masses on light microscopy and is made up entirely of a network of fibrin with adherent red cells. A quantitative relationship between the degree of aggregation of platelets and the velocity gradient *in vitro*, using a rotational cone-in-cone viscometer, have recently been demonstrated[3,4] and it was suggested that this apparatus[5] might provide a more physiological method of investigating coagulation in relation to thrombosis, as at high rates of shear the coagulation produced was identical with an arterial thrombus.

The use of a thrombelastograph[6,7], to study the blood in thrombotic states, has led to the demonstration of characteristics said to be typical of such states; namely, a shortened clotting time (r), and a rapid appearance of the point of maximal deflexion (or amplitude) of the curve (MA), producing a "tuning fork" appearance. Hartert's thrombelastograph uses a constant and low frequency of oscillation, and has a low amplitude of deflexion. The morphology of the clot obtained is a fibrin network with no visible platelet masses, and is thus characteristic of a glass tube clot[7].

Recently, one of us (L. D.) devised an oscillatory viscometer and applied it to the investigation of clotting time and viscosity of blood during coagulation[8]. It was possible to show that (*a*) the clotting time of blood decreases with the increased frequency of oscillation and (*b*) the consistency of blood clots decreases progressively with the increased frequency of oscillation applied during the process of coagulation.

This instrument, now called a variable-frequency thromboviscometer oscillates over a range of frequencies, from 1 to 300 c/min, the amplitude of oscillation of the external cone being 70°. The temperature is kept at 37° C using a mercury-contact thermometer and relay, while the measurement of deflexions of the torsion strip and thus of the inner cone is carried out in the manner previously described for the cone-in-cone viscometer[4,5,9]. Blood, obtained by venepuncture from human donors without a haematological disorder or a thrombotic state, is poured into the gap between the cones and the clotting time is observed at certain fixed frequencies of oscillation. In the present experiments, three samples were taken from each donor and usually tested at frequencies of 6·6, 33 and 166 c/min. The blood coagula obtained in each experiment were then fixed in formalin, paraffin sectioned, and stained with haematoxylin and eosin. The structure can be determined microscopically, and a quantitative estimation of the platelet masses can be carried out by means of a graduated eyepiece. This eyepiece is divided into squares which correspond to a surface area of 0·01 mm² on the specimen. A systematic scan of each slide allows determination of the number of squares occupied by platelet masses per ml. of original blood sample, and thus gives an estimate of the quantity of platelet aggregation in each experiment.

A typical record of the coagulation results obtained in this investigation is shown in Fig. 1. It is clear that the curves obtained resemble those described in the standard thrombelastograph[6]. However, in a manner analogous to coagulation in the rotational cone-in-cone viscometer[4], the clotting time decreases as the frequency (or mean rate of shear) increases. Simultaneously, the viscosity or consistency of clots falls as the frequency to which they are subjected rises. The morphology of the coagula obtained also bears a similarity to our previous findings. The number of squares representing surface area of platelet masses obtained from 1 ml. of blood is shown for each frequency in Table 1. There is a rise in area of platelet aggregates corresponding to the rise in frequency of oscillations (or mean rate of shear) at the time of the experiment. This is further shown in Fig. 2 where a gradual change and increase in platelet masses are observed, eventually producing a structure, similar to arterial thrombosis, at high oscillatory frequency. While the increase of irreversible platelet agglomeration with the rise in velocity gradient appears of great physiological interest, some questions still remain unanswered. The reduced clotting time associated with an increase in velocity gradient cannot be explained, although three suggestions might be given: first, that more effective diffusion of clotting factors might occur because of the high velocity gradient; secondly, that this effect might be due to the decreased viscosity of the original blood at higher velocity

Table 1. COAGULATION AND DEGREE OF PLATELET AGGREGATION DETERMINED BY MEANS OF THE VARIABLE-FREQUENCY THROMBOVISCOMETER

r, Clotting time, measured from the moment when the first drop of blood appears in the syringe during venepuncture to the moment when blood viscosity starts to increase; MA, maximum amplitude, arbitrary units.
* The first few cases were investigated at room temperature; all the others were tested at 37° C.

gradients; and thirdly, that some unidentified mechanochemical transformation within platelets might contribute to the higher reaction rate at high velocity gradients. The latter point might not be of paramount importance, as decrease of clotting time at higher velocity gradients has also been observed[4] in platelet-poor blood.

Hartert[6] noted that the maximal amplitude of the curves obtained in thrombelastography depends on the platelet concentration, a decrease in amplitude being related to a fall in platelet count. We cannot comment on the correlation between amplitude and platelet concentration in the multiple-frequency thromboviscometer. The amplitude was found to be greatly sensitive to changes in the frequency and rate of shear. It has been suggested that the fall in consistency with increasing frequency or

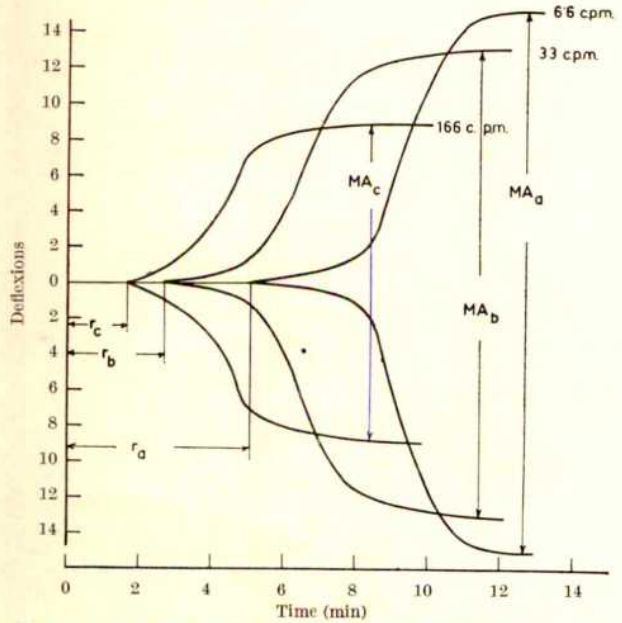

Fig. 1. Consistency of coagulating blood determined by means of the variable-frequency thromboviscometer at 37° C. MA, Maximum amplitude; r, clotting time; subscripts a, b, and c refer to the blood samples coagulating at frequencies of oscillation 6·6, 33 and 166 c/min, respectively. Please note that increasing frequency reduces both the consistency of blood coagula and the clotting times

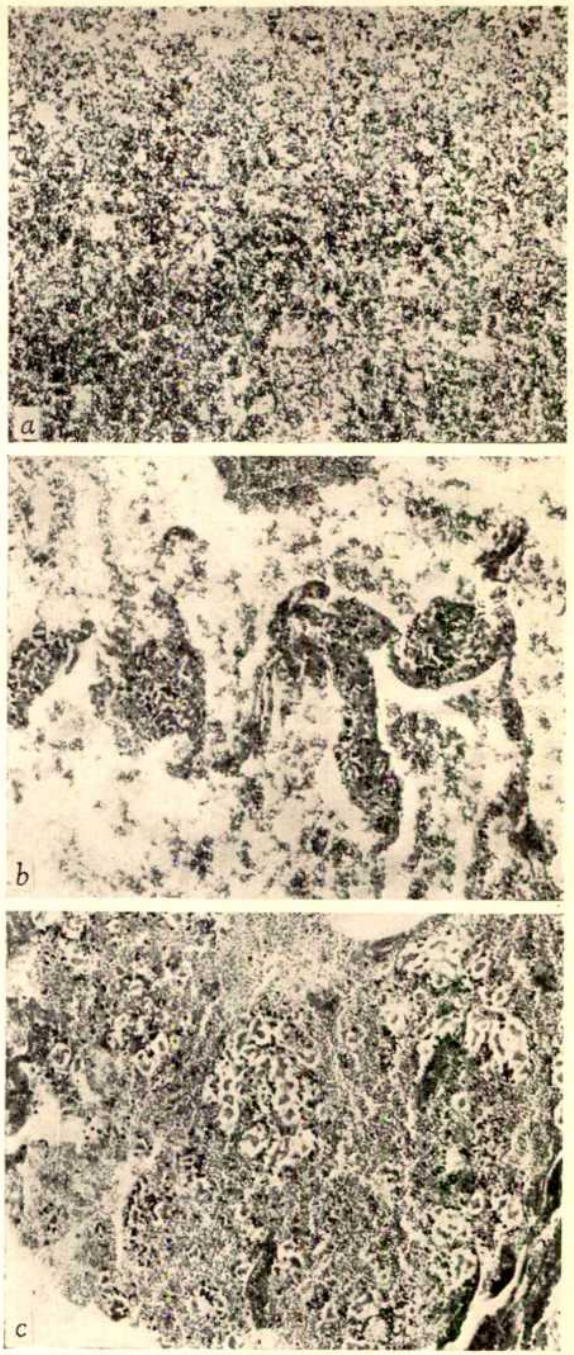

Fig. 2. (*a*) Section of coagulum obtained in thromboviscometer at 6·6 c/min. The structure consists of a fibrin layer with red cells and white cells in random distribution. The morphology is identical with a glass tube clot (× 60). (*b*) Section of coagulum obtained in thromboviscometer at 33 c/min. The fibrin network is still evident, but small amorphous masses consisting of platelet aggregates and surrounded by leucocytes are now evident in the centre of the field (× 60). (*c*) Section of coagulum obtained in thromboviscometer at 166 c/min. Amorphous masses surrounded by leucocytes are abundant and the fibrin network is reduced in quantity. This structure resembles *in vivo* thrombosis (× 60)

velocity gradient[8] reflects the variable orientation of fibrin during polymerization. This process will require further elucidation. The role of platelets in the rheology of blood coagula is rather obscure. Neither free platelets nor platelet aggregates contribute significantly to the viscosity of blood or consistency of blood coagula, respectively.

It could be added that as thrombosis is a process occurring in the body in flowing blood, any investigations related to this process should attempt to simulate these

conditions. As the morphology, consistency and clotting time in coagulation have been shown to depend on the frequency and rate of shear, the future investigation of blood coagulation in the oscillatory viscometer (variable-frequency thromboviscometer) would appear of definite value.

We thank the National Heart Foundation of Australia for supporting this work.

RADIOBIOLOGY

Radiation-induced Inhibition of Thymidine Incorporation by Mammalian Cells *in vitro*

THE influence of ionizing radiation on the metabolism of DNA has frequently been studied using radioactive precursors such as tritium- or carbon-14-labelled thymidine. In many systems the uptake of tracers into DNA was clearly suppressed according to a biphasic dose-effect curve[1–3]. However, effects of pool size have been observed as well, that is, the observed effect is reverted in increasing concentrations of the labelled thymidine. This phenomenon, first observed by Hell *et al.*[4] in ascites cells *in vitro*, was tentatively explained by the authors as a lowering of the specific activity of the tracer by DNA breakdown products. In HeLa S_3 cells, a similar concentration dependent effect was noted by Painter and Rasmussen[5], but here the effects were attributed to an impairment of the rate of DNA synthesis by high thymidine concentrations, masking some of the effects of X-irradiation.

In view of the importance of the aforementioned pool effects in elucidating the influence of ionizing radiation on DNA metabolism, the incorporation of ^{14}C-thymidine (^{14}C-TdR) into DNA of control and irradiated cells was re-investigated in graded concentrations of the tracer. The cell line used was a bovine liver strain isolated in our laboratory[6] and cultivated as a monolayer in small Carrel flasks. The medium consisted of 25 per cent calf serum and 0·5 per cent lactalbumin hydrolysate in Hanks's balanced salt solution. X-irradiation was performed with a 30 m.amp, 50 kVp unit. With filtering by the glass covering of the vessels (uniformly 1 mm thick), a dose rate to the cells was achieved of 405 r./min at a distance of 20 cm. Based on previous experience[7], thymidine incorporation was investigated within a 2 h period following irradiation with 500 r. In these circumstances, observed effects all fell within the range of the steep component of the well-known biphasic dose-response curve (denoted as the S_1 effect according to Lajtha *et al.*[1]).

Cultures containing $5 \cdot 10^6$ cells each were incubated in medium with various concentrations of ^{14}C-TdR (specific activity 30 mc./mmole) for 2 h following irradiation or sham irradiation. At the end of the incubation period, cells were trypsinized from the vessels and their DNA isolated[8]. Trypsinized cells were washed consecutively in 5 ml. of each of the following solutions: 96 per cent alcohol, 70 per cent alcohol and twice 96 per cent alcohol–di-ethyl ether (3 : 1). RNA was removed by incubation for 18 h in 0·5 N perchloric acid (PCA) at 4° C, the resulting suspension was centrifuged and the pellet washed with cold 0·5 N PCA. DNA extraction was accomplished by incubation in 1 N PCA for 45 min at 70° C. After cooling, an equimolar amount of potassium hydroxide was added and cell debris, together with insoluble potassium perchlorate, were spun off. Equal portions of the supernatant were used for the estimation of DNA using Burton's modification of the diphenylamine test[9] and for the measurement of radioactivity by means of a Geiger–Müller type counter. A comparison of the specific activities of DNA extracted with hot acid with that of DNA digested with DNase I showed that no part of the radioactivity in the acid extract originated from other sources than DNA after incubation of cells in either ^{14}C-thymidine or phosphorus-32. Incorporation rates were expressed as the specific activity of the isolated DNA. The results of a typical experiment are given in Fig. 1.

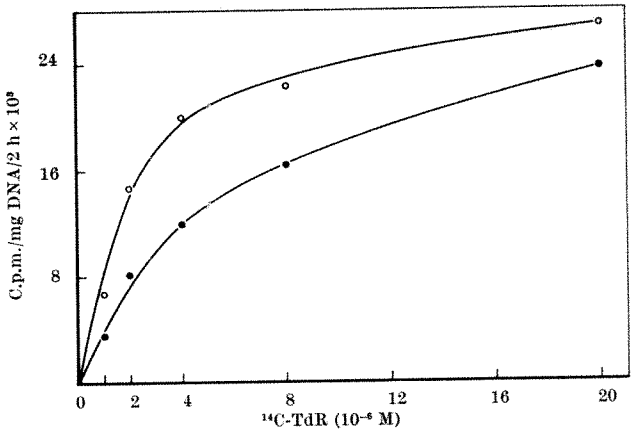

Fig. 1. The incorporation of ^{14}C-TdR at different concentrations of the tracer in control (○——○) and irradiated (●——●, 500 r.) cultures. Data are based on measurements of specific radioactivity of DNA isolated after 2 h of incubation. Each point is the average of from three to five individual determinations

Table 1. DNA SPECIFIC ACTIVITY IN CONTROL AND IRRADIATED (= 500 R.) CULTURES AFTER A 2 H PERIOD OF INCUBATION IN EITHER $^{32}P_i$ (765×10^{-6} M) OR IN ^{14}C-TdR (10^{-6} M)

Tracer used	Specific activity (c.p.m./mg DNA) control	500 r.	Change (per cent)

* Average of seven individual determinations.
† Standard deviation.
‡ Average of six individual determinations.

As expected, irradiation results in a decrease in thymidine incorporation from the medium, but it is also evident that this decrease is progressively less pronounced in series of media with increasing concentrations of exogenous thymidine (that is 50 per cent decrease at 10^{-6} M but only 10 per cent at 2×10^{-5} M). If data of Fig. 1 are represented in a Lineweaver–Burk plot[10], no significant difference can be observed between the "V_{max}" of controls and cultures receiving 500 r. (Fig. 2). The effect of irradiation in these circumstances seems to be mainly competitive inhibition in the uptake of exogenous thymidine into DNA, leaving the enzymes involved in thymidine incorporation unaffected. In addition, if we keep in mind that cells *in vitro* do not need exogenous thymidine for sustaining their synthesis of DNA, there is considerable doubt as to whether X-rays affect this synthesis at all under our experimental conditions. Therefore, instead of labelled thymidine, phosphorus-32 as inorganic phosphate (P_i) was used for studying the rate of DNA synthesis after

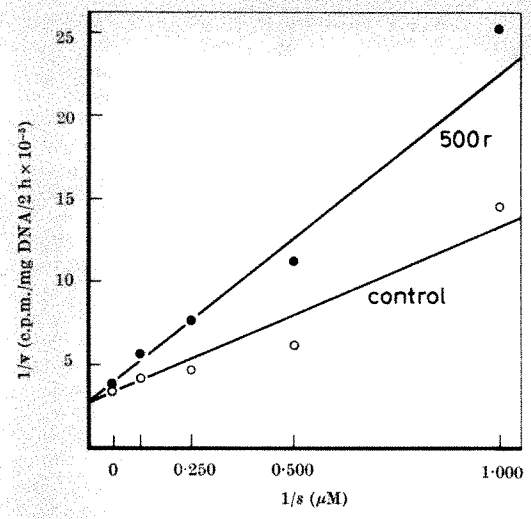

Fig. 2. Data of Fig. 1 taken as indices of ^{14}C-TdR incorporation rates and represented in a Lineweaver–Burk plot. Control, $V_{max} = 4{\cdot}0 \times 10^4$ c.p.m./mg DNA/2 h. 500 r., $V_{max} = 3{\cdot}9 \times 10^4$ c.p.m./mg DNA/2 h

500 r. The label was added as carrier-free phosphorus-32-labelled potassium dihydrogen phosphate to obtain 0·5 μc. per ml. culture fluid. Total concentration of inorganic phosphate in this medium was 765×10^{-6} M, high enough to swamp out any pool effect. For this reason, $^{32}P_i$ is considered to be a more accurate tracer for determining DNA synthesis. As can be seen in Table 1, no decrease of phosphate incorporation is observable after 500 r. as compared with the incorporation of labelled thymidine (at 10^{-6} M concentration).

These observations are consistent with our assumption of an unchanged rate of DNA synthesis after irradiation (so far as the S_1 effect is concerned). In explaining their finding of a thymidine dependent reversal of the effect of irradiation, Painter and Rasmussen[5] attributed this effect to an influence of high thymidine concentrations on the rate of DNA synthesis in HeLa S_3 cells. For my cell line, however, this possibility could be ruled out. The uptake of $^{32}P_i$ into DNA was investigated at various concentrations of non-radioactive thymidine up to 30×10^{-6} M over 2 h, but I was not able to detect any decrease in the rate of incorporation. My results then, namely, a competitive inhibition of thymidine incorporation together with an unchanged rate of DNA synthesis, can be explained by assuming that the endogenous (and thus non-radioactive) pools of thymidine are augmented after irradiation as a result of DNA breakdown according to the hypothesis of Hell *et al.*[4]. These breakdown products will compete with labelled substrate for incorporation into DNA and decrease the uptake from the medium in lowering concentration gradients.

The questions arise as to why so few reports on pool effects exist and why Hell *et al.*[4] were able to detect them only in ascites cells and not in bone marrow cells *in vitro* and in mouse thymus cells *in vivo*. Though far from suggesting that this effect is a general one, one nevertheless could offer a reason for the inability to detect pool effects in some cases. First of all it will be clear that exogenous thymidine concentrations have to be varied within a range where there exists some proportionality between concentration and incorporation rate. From the data of Marin and Bender[11] it can be deduced that in HeLa S_3 cells *in vitro*, maximum incorporation rates already occur at thymidine concentrations of 2×10^{-6} M. Using these HeLa S_3 type cells, Painter and Rasmussen detected concentration dependent effects at 0·15 and 10×10^{-6} M thymidine[5], but no differences[12] in a range of $15–40{,}000 \times 10^{-6}$ M, which might be explained by assuming that in the latter series the maximum rate of incorporation had already been reached at the lowest concentration tested. Furthermore, in my cell strain, maximum incorporation rates only occur at concentrations of 20×10^{-6} M or higher (see Fig. 1), which suggests that there are considerable differences between the abilities of cell strains to use exogenous thymidine in the synthesis of DNA. In view of these differences it seems appropriate to investigate whole "Michaelis–Menten" curves[10] in detecting (or excluding) pool effects after irradiation.

Distribution of Caesium and Rubidium in Human Blood

DURING an investigation of the total body burden of caesium-137 in human beings[1], the caesium-137 content of various samples of blood was analysed. About 100 ml. of blood taken from male subjects was heparinized and centrifuged for 10 min at 3,000 r.p.m. Twenty mg of carrier caesium was added to the plasma and erythrocyte fractions, and the content of caesium-137 determined radiochemically[2]. The results (Table 1) for two subjects on three occasions show a fairly consistent ratio of 1 : 3 for the caesium-137 content of the plasma to that of the erythrocytes.

The sodium and potassium metabolism of erythrocytes has been extensively studied and it is known that the greater part of the latter, more than 90 per cent, is located in these cells. Rubidium and caesium are members of the heavy alkali metals and resemble potassium in many of their chemical and biological properties. Nevertheless, the distribution pattern found for caesium-137 (a fall-out product of nuclear explosions which becomes incorporated in man) differs from that of potassium.

From *in vitro* tracer experiments, Love and Burch[3] found that rubidium and potassium were incorporated in human erythrocytes. To confirm the possibly different distribution in blood *in vivo* of caesium to potassium and rubidium, stable caesium and rubidium were measured by the neutron activation followed by gamma spectrometry[4] in blood fractions taken from subjects by the method described previously. The results are shown in Table 2. Ninety-eight per cent of the rubidium present in blood is located in the erythrocytes. This supports the findings of Love and Burch, but disagrees with those of Bertrand and Bertrand, who reported that the erythrocytes contained about three times as much rubidium as did plasma[5].

The whole blood concentration of rubidium was found to be fairly constant in four individuals (1·6–2·0 mg/kg) and came within the range reported by Bertrand and Bertrand (1·63–4·95 mg/l.)[6]. The relative variation of the whole blood concentration was much greater for caesium than for rubidium, and came to 1 : 10, and the range of the rubidium : caesium ratio in individuals is from 5 to 39. The average ratio of the contents of caesium in the plasma to that in erythrocytes is 1 : 3, which is in good agreement with that found for caesium-137.

Table 1. DISTRIBUTION OF CAESIUM-137 IN HUMAN BLOOD

6/65	Iw	35·0	20·3	79·7
			Av. 25·1 ± 3·8	74·9 ± 3·8

Table 2. DIFFERENT DISTRIBUTION OF STABLE CAESIUM and RUBIDIUM IN HUMAN BLOOD

	Subject	Concentration in Whole blood (p.p.m.)	Plasma (per cent)	Erythrocytes (per cent)
Rubidium	Ku	1·8	< 2·3	> 97·7
	Ya	2·0	3·2	96·8
	Ar	1·6	< 2·3	> 97·7
	Iw	1·8	< 2·1	> 97·9
Caesium	Ku	0·046	26·0	74·0
	Ya	0·40	40·4	59·6
	Ar	0·042	24·3	75·7
	Iw	0·13	11·8	88·2

It is generally accepted that potassium, rubidium and caesium are univalent ions of intracellular importance, which is in contrast to sodium, which is distributed extracellularly throughout the body. However, it has been pointed out by numerous workers that while rubidium closely resembles potassium in many of its chemical and biological properties and metabolic pathways, caesium does not. The difference between rubidium and caesium cannot be attributed to differences in ionic radii, ion-exchange and adsorptive properties. An example of this is the distribution study of the heavy alkali elements in soil and native plants[7]. A greater variation in the ratio of caesium : potassium was found in plants as compared with that for rubidium : potassium. The existence of any correlation between the caesium and potassium contents of plants is doubtful ($r = 0{\cdot}18$); however, in contrast, a good correlation is found between rubidium and potassium ($r = 0{\cdot}72$).

The present investigation has been confined to the static aspect of the distribution in human blood. A dynamic study by means of radioactive tracers *in vivo* in human beings is being carried out in the hope of demonstrating metabolic difference between caesium and rubidium or potassium.

BIOCHEMISTRY

Interaction of Actin and Myosin during Clearing

SUPERPRECIPITATION of actomyosin has long been thought to involve both binding of the actin to the myosin and activation of the myosin adenosine triphosphatase (ATPase) by actin in the presence of magnesium[1]. The clearing response, on the other hand, has been reported to result from dissociation of the actomyosin with a concomitant loss of this ATPase activation[2]. In both situations, the physically observable binding and the activation of the myosin ATPase by actin were thought to change in parallel[3], but some recent observations have been difficult to reconcile with this conclusion. In investigating the effect of tropomyosin *B* on actomyosin, A. M. Katz[4] noted that actin can activate the myosin ATPase without superprecipitation occurring. In other investigations, Leadbeater and Perry[5], and Perry and Cotterill[6], found that actin activates the ATPase of heavy meromyosin under conditions where viscosity measurements indicated that the two proteins might be dissociated. Extrapolating these data to the actomyosin system, Perry *et al.* argued that the interaction of actin and myosin which results in activation of the myosin ATPase is not accompanied by physical interaction as strong as that which occurs between the two proteins in the absence of adenosine triphosphate (ATP). Maruyama and Gergely[2], however, noted that actomyosin undergoes a brief viscosity increase simultaneously with the rise in ATPase just before superprecipitation, which suggests that strong physical interaction does accompany the activation of the myosin ATPase by actin.

In the present investigation we compared the turbidity, ATPase, and viscosity of actomyosin at various ionic strengths to determine, first, to what extent clearing represents dissociation of the actin from the myosin, and second, whether it is possible to demonstrate activation of the myosin ATPase by actin in the absence of measurable physical interaction between the two proteins.

Myosin was prepared by the method developed by Szent-Györgyi[1] and actin by the method of Ulbrecht *et al.*[7], with the extraction from the acetone-dried powder carried out at 0° C in order to avoid contamination with tropomyosin[8]. Turbidity was measured as absorbance at 675 mμ[9], ATPase activity was recorded with a *p*H-stat, and viscosity was determined with an Ostwald viscometer having an outflow time for water of about 1 min. In all cases, the reaction was initiated by the addition of myosin and the reported measurements were taken within three minutes thereafter. For all measurements the temperature was regulated at 25° C. The absorbance, ATPase, and viscosity (log $\eta_{rel.}$) of the actomyosin samples are presented in Table 1 as multiples of the theoretical values which would be expected in the absence of interaction between the two proteins. This theoretical value for each parameter is calculated as the sum of its values for actin and myosin individually[1], which in turn were measured under conditions identical to those used in the corresponding actomyosin experiments.

Table 1. TURBIDITY, ATPASE AND VISCOSITY OF ACTOMYOSIN*

Conc. of potassium chloride (M)	Clearing time (min)	Multiples of theoretical values† A_{675}	ATPase	Log $\eta_{rel.}$
0·50	—	1·0	1·0	1·01
0·13	31	1·1	3·5	1·07
0·12	18	1·0	4·5	1·20
0·105	12	1·0	5·5	1·30
0·0925	6	1·0	9·5	1·53
0·0925 (after superprecipitation)	—	~ 8·0	~ 20·0	—
0·50 (no ATP)	—	—	—	2·62

* All samples contained 2 mM ATP, 1 mM magnesium chloride, 10 mM imidazole buffer (*p*H 7), 2 mg/ml. myosin, 0·5 mg/ml. actin, and potassium chloride as indicated, in a total volume of 7·5 ml. Myosin was added last and all measurements were made within 3 min after the start of the reaction. Clearing times were determined as the time from the start of the reaction until half-maximal turbidity was reached.

† The theoretical values were approximately as follows: $A_{675} = 0{\cdot}10$; ATPase = 0·01 μmole/min.mg myosin; log $\eta_{rel.} = 0{\cdot}23$.

It can be seen in Table 1 that the turbidity of the actomyosin suspension is in every case equal either to the theoretical value for no interaction, which represents clearing, or to a value seven to eight times higher, which represents superprecipitation. However, as the ionic strength is reduced under conditions where the actomyosin remains completely cleared, the ATPase activity rises to a value considerably higher than that of the myosin alone under identical conditions. This confirms the observation of A. M. Katz[4] that actin can activate the myosin ATPase without superprecipitation, and furthermore, our data indicate that as much as ten-fold activation can occur during clearing as compared with the approximately twenty-fold activation which occurs during superprecipitation.

To determine whether physical interaction of the actin and myosin accompanies this ATPase activation, the viscosity of the cleared actomyosin was measured. As shown in Table 1, the increase in the myosin ATPase was accompanied in all cases by a parallel increase in log $\eta_{rel.}$ to values considerably higher than that expected theoretically. As these measurements were taken within 3 min of the start of the reaction, it is evident from the clearing times that the elevated viscosity is not limited to the period just prior to superprecipitation. Furthermore, this viscosity increment during clearing can reach an appreciable fraction of that observed at high ionic strength in the absence of ATP.

From these observations it can be concluded that, although actomyosin can be completely dissociated during clearing under certain conditions[2], under other conditions both physical binding of the actin to the myosin and activation of the myosin ATPase can occur with the system remaining completely cleared. Furthermore, ATPase activation during clearing was always accompanied by the formation of bonds between the two proteins sufficiently strong to give rise to a parallel increase in viscosity, thus suggesting that the interaction which leads to ATPase activation is comparable in strength to that which causes the viscosity increase in the absence of ATP at high ionic strength.

This investigation is supported by a research grant from the National Institutes of Health, U.S. Public Health Service. In addition, one of us (E. E.) is a postdoctoral fellow of the National Institutes of Health.

Acetylcholine and the Incorporation of [^{32}P] Phosphate into Phospholipids and Phosphoproteins of Nerve Endings of Developing Rat Brain

IT has been shown that acetylcholine stimulates the incorporation of [^{32}P] phosphate into the phospholipids of slices, homogenates, and microsomal fractions of guinea-pig cerebral hemispheres under conditions of oxidative phosphorylation[1,2]. Maximal stimulation of phosphorus-32 incorporation was found to occur in phosphatidic acid and phosphoinositide[2].

In a previous communication on the *in vivo* incorporation of phosphorus-32 into the lipids and proteins of the subcellular fractions of developing rat brain, the phospholipids of the nerve endings fraction were found to have the lowest specific activity[3].

In the present *in vitro* experiments, investigations were undertaken to determine the influence of exogenous acetylcholine, in the presence of physostigmine, on the incorporation of phosphorus-32 into both phospholipids and phosphoproteins of the nerve endings of the adult and developing rat brain. It was found that concentrations of the order of 10^{-4} M–$4{\cdot}75 \times 10^{-4}$ M acetylcholine inhibited the incorporation of phosphorus-32 into both lipids and proteins.

Nerve ending fractions were isolated from the conventional mitochondrial preparations by means of density gradient centrifugation in a Ficoll medium as was previously described[3,4].

Incubations were carried out in a medium containing: 10 mM pyruvate, 1·22 mM malate, 0·54 mM adenosine triphosphate, 0·5 mM cytidine diphosphate, 0·5 mM guanosine triphosphate, 0·1 mM nicotinamide-adenine dinucleotide, 0·006 mM cytochrome *c*, 6·7 mM magnesium chloride, 6 mM nicotinamide, 6·7 mM potassium fluoride, 3·7 mM glucose, 12·5 mM potassium phosphate buffer (*p*H 7·5), 0·11 mM ethylenediamine tetraacetic acid, 100–350 μc. of phosphorus-32. When added, acetylcholine and physostigmine were each $4{\cdot}75 \times 10^{-4}$ M or 10^{-4} M. All incubations were carried out at 37° C for 1 h with shaking in a final volume of 3·2 ml., and contained the nerve endings fraction, which corresponded to 0·3 g of wet brain. The Ficoll was washed off with distilled water before adding the nerve endings to the reaction mixture. This step probably removed the labile acetylcholine from the synaptosomes[5].

At the end of incubation 2 ml. of chilled 10 per cent trichloroacetic acid were added to the incubation mixture. Analytical techniques, and the techniques used for the removal of contaminating phosphorus-32, extraction of lipids, nucleic acids, thin-layer chromatography, paper electrophoresis, autoradiography, and determination of specific activity have already been described[3].

Results on the effect of acetylcholine on the incorporation of phosphorus-32 into phospholipids and phosphoproteins are shown in Table 1. In the presence of $4{\cdot}75 \times 10^{-4}$ M acetylcholine, there was an inhibition of phosphorus-32 incorporation up to 40 per cent into phospholipids and up to 42 per cent into phosphoproteins.

At a lower concentration of acetylcholine (10^{-4} M), inhibition of phosphorus-32 incorporation into phospholipids, but not phosphoproteins, was increased (Table 1). Physostigmine alone (10^{-4} M or $4{\cdot}75 \times 10^{-4}$ M) had no effect on the incorporation of phosphorus-32. In a previous investigation[4] of the developing rat brain, the presence of nerve endings was demonstrated in the embryonic stage. Because the nerve impulse appears 10 days post partum in rat brain[6], the present finding that acetylcholine has similar effect on the incorporation of phosphorus-32, regardless of age, could suggest a regulatory function for this neurohormone on phosphate metabolism in nerve endings, in addition to that of synaptic transmission. It is interesting to note that Hokin *et al.*[7], working with guinea-pig adrenal medulla, observed an inhibitory effect of acetylcholine (10^{-3} M) on the incorporation of phosphorus-32 into phospholipids.

Table 1. ACETYLCHOLINE EFFECT ON LABELLING OF LIPIDS AND PROTEINS OF NERVE ENDINGS WITH PHOSPHORUS-32 [PHOSPHATE]

	Specific radioactivity of lipids					Specific radioactivity of proteins × 10^{-3}				
Age in days	Control	Acetylcholine $4{\cdot}75 \times 10^{-4}$ M (c.p.m./μmole P)	10^{-4} M	Δ	Inhibition (per cent)	Control	Acetylcholine $4{\cdot}75 \times 10^{-4}$ M (c.p.m./mg N)	10^{-4} M	Δ	Inhibition (per cent)

Plates were exposed to iodine vapour, and the spots counted. *A*, *B*, Acetylcholine omitted and present respectively. 1, Phosphorus-32 and proteolipids (*A*, *B*, 864 c.p.m., 180 c.p.m., respectively); 2, lysophosphatidyl choline (776, 132); 3, sphingomyelin (756, 132); 4, phosphatidyl choline (916, 148); 5, phosphatidyl inositol (1772, 328); 6, phosphatidyl serine (242, 48); 7, phosphatidic acid (160, 44)

Fig. 2. Autoradiograph of an ionopherogram of a phosphoprotein hydrolysate of nerve endings of 12-day-old rats. The phosphoprotein was hydrolysed in 12 N hydrochloric acid at 38° C for 24 h. Electrophoresis was run at *p*H 3·3, pyridine–acetic acid–water buffer, 6,000 V-h. *A*, Acetylcholine omitted; *B*, acetylcholine added. 1, 2, 3 and 4, Phosphopeptides; 5, phosphothreonine; 6, phosphoserine; 7, phosphorus-32

Acetylcholine, in concentrations of the order of 10^{-4} M or $4{\cdot}75 \times 10^{-4}$ M, had no effect on the incorporation of serine uniformly labelled with carbon-14 serine into phospholipids or phosphoproteins.

When the phosphorus-32-labelled phospholipids were run in one-dimensional thin-layer chromatography[8], phosphatidyl inositol had the highest activity in the presence or absence of acetylcholine (Fig. 1). Ionophoresis of phosphoprotein hydrolysates (Fig. 2) at *p*H 3·3, together with phosphoserine and phosphothreonine controls, revealed the presence of phosphorus-32-labelled phosphoserine and phosphothreonine as well as phosphorus-32-labelled phosphopeptides. There was little labelling of phosphoproteins and phospholipids when the ingredients of oxidative phosphorylation were omitted. This labelling could arise from the fact that nerve endings contain a high concentration of 'stable' ATP (ref. 9).

The inhibitory effect of acetylcholine on this formation of ATP as measured according to the procedure of Crane and Lipmann[10] was negligible, and ATP had a specific activity 7–10 times as high as that of phosphoproteins. Also acetylcholine and physostigmine ($4{\cdot}75 \times 10^{-4}$ M) had no effect on the phosphorus : oxygen ratio[11].

The foregoing results confirm previous *in vivo* observations[3], which indicated that nerve endings incorporated phosphorus-32 at a lower rate than the other subcellular fractions. Thus, it is possible that the inhibitory effect of acetylcholine observed in the present *in vitro* investigations could occur *in vivo*.

Low Molecular Weight Carbohydrates in Urine from Secretors and Non-secretors of Different Blood Groups

IT has been shown that gel-filtration is a useful method for the fractionation of ultrafilterable substances in normal urine. At least six carbohydrate fractions have been obtained from concentrated urine ultrafiltrates by means of gel-filtration on 'Sephadex *G*-25'[1]. The general pattern of these fractions from pooled urine was found to be fairly constant, but some variations were observed in individual urines. Recently, it was shown that secretors of A-, B- and H-substances show a considerably higher excretion of fucose in gastric mucus and urine than non-secretors[2,3]. This communication describes some differences in the excretion of low molecular weight fucose-containing components that have been detected in the urine of secretors and non-secretors belonging to various blood groups by a comparison of the gel-filtration patterns of their urine ultrafiltrates.

Urine produced during 4 h in the morning after starvation for 16 h was collected from seventy-two healthy male individuals, selected according to their blood group and secretor status. Phenylmercuric nitrate was added to a final concentration of 1 : 50,000 in order to prevent bacterial growth. The urine samples were filtered at +4° C and analysed for fucose and hexosamine. Secretors belonging to blood groups A_1, B and O were found to have a higher fucose excretion than non-secretors. The difference was of the same magnitude as was previously shown for individuals belonging to A and O groups[3]. There was no significant difference, however, in the hexosamine excretion between secretors and non-secretors. Four-hour urine samples from three or four individuals of each blood group and secretor status were then ultrafiltered through Visking dialysis tubing (23/32 in flat width). On average, 80 per cent of the hexosamine and fucose material could be ultrafiltered. The ultrafiltrate from each individual was concentrated ten times by means of a rotating flask evaporator. At the most, only 10 per cent of the fucose and hexosamine material was lost during the concentration. Seven ml. of each urine sample was then applied to a 'Sephadex *G*-25' column (2·9 × 140 cm), and eluted with distilled water. The eluates were analysed for total hexose, fucose, sialic acid, hexosamine, uronic acid and protein. The methods used were those described earlier[1].

Individuals of various blood group and secretor status gave very similar sialic acid-, hexosamine-, uronic acid- and protein-curves. These curves closely resembled the earlier ones obtained for pooled urine[1]. Examination of the distribution of the total hexose and fucose materials, however, revealed four types of patterns, as can be seen from Fig. 1. There was one non-secretor pattern, obtained

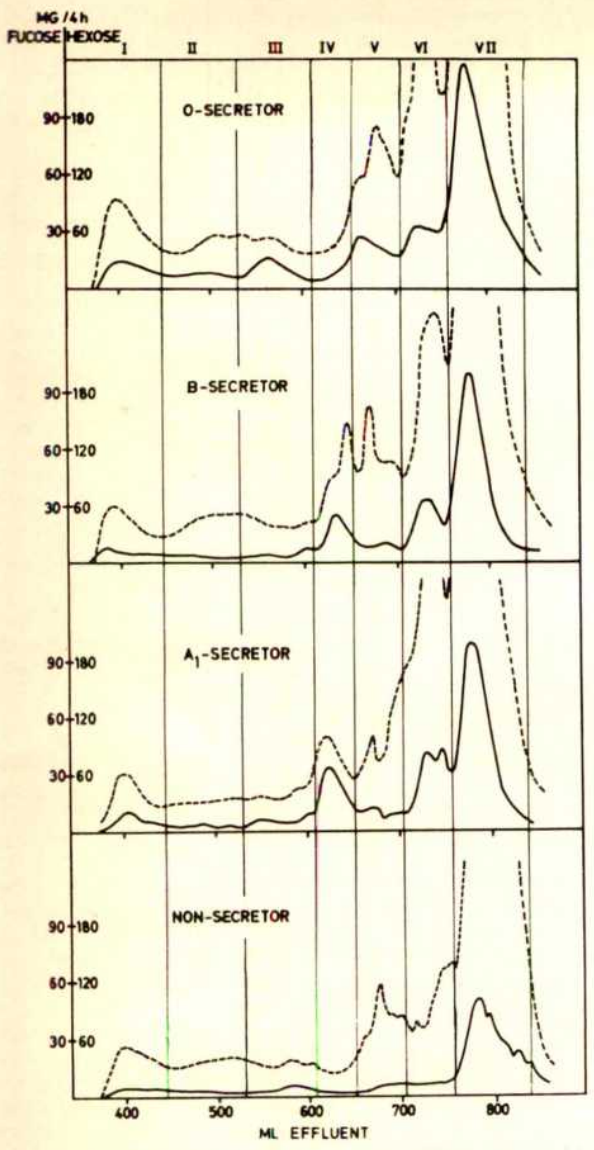

Fig. 1. Fucose (——) and total hexose (– – – –) patterns obtained by gel-filtration on 'Sephadex *G*-25' of urine ultrafiltrates from individuals of various blood groups and secretor status. The eluant was distilled water

from individuals of blood groups A_1, B and O. Individuals having the same blood group and secretor status displayed almost identical patterns. The non-secretor pattern had a low fucose level and a high and broad peak in region VII, whereas the spectra obtained with urine from secretors were all characterized by distinct fucose peaks in both the VI and VII regions. An additional fucose peak was found in region V from O-secretors and in region IV from A_1- and B-secretors; however, the peak from B-secretor urine was eluted somewhat later than that from A_1-secretor urine. Small elevations of the curve were found in regions I and III from both secretors and non-secretors. The total hexose curve followed the fucose curve except in region V in A_1- and B-secretors and regions V and VI in non-secretors, where a high hexose-level occurred without a corresponding elevation of the fucose curve. Preliminary investigations concerning the material in region IV from A_1-secretors showed that the main part of the carbohydrate material in this region was neutral. After paper chromatography, the material did not react with ninhydrin.

So far, only a few serological tests have been performed with the fractions obtained. A slight inhibition of anti-A-serum was observed with the material in region IV from A_1-secretors, whereas anti-B and anti-H were not inhibited by this material. Material in region V from O-secretors inhibited anti-H very slightly, whereas material in region V from A_1-secretors did not show this property.

A more detailed characterization of the various carbohydrate fractions described here is being carried out.

HAEMATOLOGY

Human Serum Enzymes in Electrophoretic Fractions

SOME of the electrophoretic components of human serum have been shown to contain certain enzyme activities[1,2].

As human serum is known to contain a number of enzymes such as cholinesterase, lipase, transaminases, amylase and phosphatases, it was decided to find the positions of the different serum enzymes after electrophoretic separation of the protein components.

Electrophoretic separation of normal human serum was carried out using 0·5 per cent agar (Difco Laboratories) in 0·05μ veronal buffer, *p*H 8·6, for 6 h with a current of 1 mamp/cm. After electrophoresis one strip was stained with amido-black 10*B* (saturated solution in solvent; composition: methanol, distilled water, acetic acid; 50 : 50 : 10, v/v)[3]. On the other strip, 1 per cent of soluble starch in the same veronal buffer was applied uniformly by a filter paper soaked in the starch solution for 5 min. The electrophoretic strip was incubated at 30° C in a water-saturated cabinet for 1 h. After this, the electrophoretic plate was carefully sprayed with dilute iodine solution in potassium iodide. Blank areas showing the digested starch appeared against the blue background of the undigested starch. The results are given in Fig. 1.

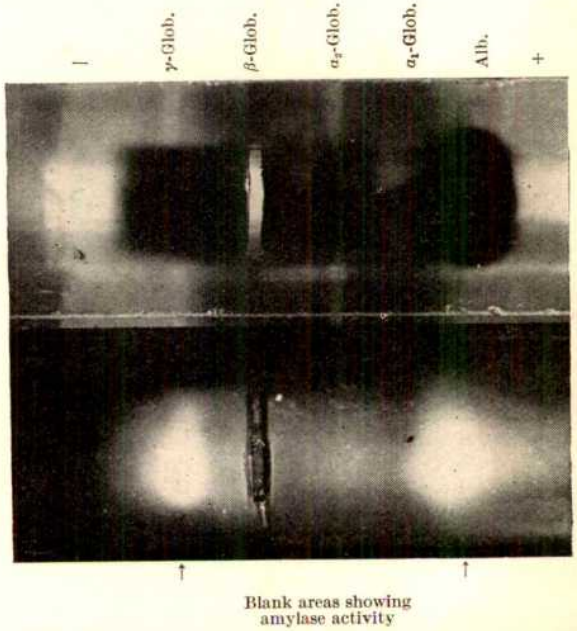

Fig. 1. Agar electrophoresis of human serum and detection of amylase. Upper strip stained with amido-black 10*B*, and lower strip stained with starch solution

It can be seen that there are two very intense zones of amylase activity in the albumin and γ-globulin fractions; faint bands can also be seen in α_2- and β-globulin fractions. Human serum thus seems to contain more than one component with amylase activity.

It is interesting to note that M. Ataur Rahman[4] has detected serum amylase activity in the globulin region only, whereas McCeachin and Potter[5] found serum amylase mostly in the albumin region. The present communication shows amylase activity both in the albumin and in the γ-globulin regions.

In another experiment serum glutamate oxalacetate and serum glutamate pyruvate transaminases were found to appear in sodium chloride (0·9 per cent) eluates of 1-cm segments of electrophoretic strip corresponding to the albumin, α_2- and β-globulin fractions. The estimations of these enzymes were carried out according to the method of King[6].

All these experiments were repeated several times and the same results were obtained. More detailed investigations of the electrophoretically distinct amylases of normal human serum and other enzymes will be reported elsewhere.

One of us (V. B. K.) thanks the Government of India for the award of a scholarship. We thank Dr. J. W. Airan for his kind interest in this work.

Cytogenetic Studies in Twins, one with Chronic Granulocytic Leukaemia

CHROMOSOMAL investigations of a patient with chronic granulocytic leukaemia and his normal identical twin were reported by Goh and Swisher[1]. While some cells cultured from the peripheral blood of the patient contained the Philadelphia chromosome, those from the peripheral blood and the bone marrow of the normal twin did not show the abnormality. The authors comment on the extreme rarity of this finding; however, we now record a second example.

E. F., a male born in 1928, a few minutes before his identical twin F. F., was diagnosed as having chronic granulocytic leukaemia in May 1963. In December 1962 the patient had a severe haemorrhage following removal of his tonsils. After the operation he did not regain his usual good health and in May 1963 he was referred to hospital for investigation. Pallor and hepatosplenomegaly were recorded on physical examination, and a blood test indicated chronic granulocytic leukaemia. Cytogenetic investigations were positive for the Philadelphia chromosome (Table 1). The patient has since been responding well to radiotherapy and chemotherapy.

Further investigations were envisaged when we became aware that he had a twin brother. The twin (F. F.) consented in May 1964 to a blood examination but not at that time to a bone marrow aspiration. Cytological and cytogenetic investigations revealed no abnormalities in his blood, and a comparison of his groups (ABO, Rh, MNS and Kell) with those of our patient confirmed the clinical and family impressions that they were identical twins.

No significance could be attached to the absence of the Philadelphia chromosome in the cells cultured from F. F.'s peripheral blood as it contained no primitive myeloid cells. Recently, however, he consented to a bone marrow aspiration and twenty-five clear metaphases have been investigated. They do not contain the Philadelphia chromosome. This is significant and confirms the fact, already deduced from other data, that the Philadelphia chromosome is not present in the zygote but must develop later. It also suggests that environmental factors are more important than hereditary factors in the development of this chromosomal abnormality.

Table 1. CYTOGENIC EXAMINATIONS

Subject	Date	Material	Metaphases No. examined	Metaphases No. Ph¹ + ve
E. F.	6.6.63	Peripheral blood culture (92 h)	42	21
	9.12.63	Peripheral blood culture (72 h)	23	8
	27.8.64	Peripheral blood culture (74 h)	28	3
	28.6.65	Bone marrow direct	10	10
F. F.	29.5.64	Peripheral blood culture (96 h)	25	0
	25.6.65	Bone marrow direct	25	0

The possibility, should the disease become acute, of treating our patient with high doses of total-body radiation has been made practicable by his twin's offer to donate marrow.

Oxygen Dissociation of Sheep Haemoglobins A and B in Solution

Two distinct electrophoretic types of sheep haemoglobin have been identified by Harris and Warren[1]. They designated the fast-moving component which travelled towards the anode at *p*H 8·6 'haemoglobin A', and the slow-moving one 'haemoglobin B'. Similar electrophoretic differences were found with adult haemoglobins in Dutch sheep by Helm *at al.*[2], which they named HbI and HbII, corresponding to HbB and HbA respectively. Further differences in chromatographic behaviour, in resistance to denaturation by alkali, in solubility in concentrated salt solutions and in amino-acid composition were demonstrated for HbI and HbII[2]. The oxygen equilibrium curves of these haemoglobins were also found to be different[3,4], HbII(A) having a higher affinity for oxygen than HbI(B), and it has been suggested that HbII(A) originated in sheep living at high altitude.

The kinetic dissociation constant, k_4, of the reaction $Hb_4O_8 \rightarrow Hb_4O_6 + O_2$, can be measured by the carbon monoxide displacement method of Gibson and Roughton[5], though in practice it is inconvenient as four or five experimental determinations have to be made, and the result obtained by an extrapolation procedure. At *p*H 9·1, this constant can be more easily measured by mixing a dilute solution of oxyhaemoglobin with 0·4 per cent sodium hydrosulphite dissolved in a buffer solution equilibrated with 1 atmosphere of carbon monoxide[6]. Kernohan[4,7], using the latter method, has attributed the difference in oxygen affinity between HbII(A) and HbI(B) to variation in their rate of dissociation—the respective mean values of k_4 being 40·6 ± 2·5 sec^{-1} and 57 ± 3 sec^{-1} at *p*H 9·1 and 20° C. Though a comparison of the sodium hydrosulphite method with the displacement technique gave good agreement at *p*H 9·1 (ref. 6), hydrosulphite is known to attack haemoglobin[8,9] and is not applicable to the lower *p*H range. Recent work has also

suggested that errors may arise from changes of light transmission and refractive index when hydrosulphite is dissolved in solution.

An alternative method, primarily developed for measuring the rate of dissociation in red blood cells, has been used to examine this problem further. A buffer solution of oxyhaemoglobin at *p*H 9·1, in equilibrium with oxygen at a pressure of 10–40 mm mercury, is rapidly mixed and at the same time diluted 1 : 20 with a similar buffer solution equilibrated with carbon monoxide at 800 mm mercury. Dissociation of the HbO_2 occurs with rapid uptake of carbon monoxide, under conditions similar to the displacement method of Gibson and Roughton[5]. The relative ratio of the concentrations, $[O_2]/[CO]$, after mixture, however, is now such that the rate is determined by $k_4/4$ to within 2 per cent. In practice this is within the experimental errors and no significant difference in the rate of egress can be detected with a four-fold change of oxygen tension or a three-fold change of carbon monoxide concentration. A comparison of this method with the hydrosulphite technique has revealed no significant error. The method can also be applied to measurements at lower *p*H.

With HbII(A), the electrophoretically fast component, the value of k_4 at 20° C and *p*H 9·2 was 40·8 ± 7 per cent by the sodium hydrosulphite method, and 38 ± 7 per cent by the dilution technique. At *p*H 7·4, k_4 was 44·5, higher by a factor of 1·1 in accord with the observations of Gibson and Roughton[5]. The activation energy at both *p*H values was 19·5 kcal ± 7 per cent. Similar measurements on an electrophoretically pure form of HbI(B), at *p*H 9·2, gave a value of k_4 = 45 at 20° C by both methods. The activation energy in this case was 16·5 kcal ± 7 per cent. At *p*H 7·4, using the dilution technique, k_4 at 20° C was 54·8 and the activation energy had increased to 19 kcal.

The values of k_4 for HbII(A) are, within experimental error, the same as those obtained previously[4,5]. In the case of HbI(B), however, an interesting discrepancy has occurred. The value at *p*H 9·2 is not the same as that obtained by Kernohan[4], though the value at *p*H 7·4 is only slightly lower. On the other hand, it had been assumed that the values of k_4 obtained by Gibson and Roughton[5] were those of HbII(A), though while at *p*H 7·1 only activation energies of the order 20 kcal were obtained, at *p*H 9·1 two distinct values occur one at 16·5 kcal and another at 20 kcal. It now seems probable that the 16·5 kcal measurements were made on HbI(B) samples. A similar difference in the rate of egress with *p*H change has been observed for this haemoglobin within intact red blood cells, so that the discrepancy is unlikely to be associated with the method of preparation of the haemoglobin solution.

The differences at *p*H 9·2 do not affect Kernohan's conclusion that the shift of the oxygen equilibrium curves observed by Huisman *at al.* is associated with differences in k_4, but the question arises as to whether HbI and HbB are identical, or whether there are two forms of the electrophoretically slow HbI(B) sheep haemoglobin.

HISTOLOGY

A Simple Dye Test for Skin Graft Viability

PATENT blue V dye (alphazurine 2*G*), which was previously used in evaluations of cutaneous burns[1], has also been found useful in the evaluation of the viability of allografted skin before and including the process of rejection. In small animals, dye injected intravenously provides immediate colouring of the skin over an intact vasculature.

The autograft after revascularization will be coloured light blue, the same as the surrounding skin. With increased vascular permeability as occurs in second degree burns or early rejection, the dye is deposited extravascularly as a dark blue stain, enabling the observer to locate the area of vascular disruption. With coagulation necrosis and thrombosis as found in third degree burns, or total allograft rejection, no tissue colouring occurs, and this demarcates the non-viable skin.

In very small animals, the dye can be injected intraperitoneally, but a 5–10 min lag period must be allowed for the full dye pattern to develop. Dye patterns should be read shortly after the skin has reached its maximum colour, as patent blue will in time diffuse into non-vital areas. This latter phenomenon provides a "reciprocal pattern" for confirmation while the intravascular dye is being rapidly metabolized by the liver and excreted through the kidneys.

This test may be repeatedly carried out without disturbing the graft to follow the process of rejection or its suppression. The histological changes occurring during rejection are not delineated in detail by this technique, but sequential information concerning the vascularization of the graft is obtained, and this bears directly on survival.

There are many possible clinical applications of this technique, but care should be taken in using this experimental agent in debilitated patients.

PHYSIOLOGY

Structure and Function of the Sarcolemma of Skeletal Muscle

THE functions of the sarcolemma of skeletal muscle are still uncertain, because of our lack of knowledge of its structure and detailed distribution over the entire surface of the muscle cell. Most of our knowledge is derived from electron microscope investigations and the sarcolemma is regarded as a semi-permeable unit membrane about 100 Å thick, which directly encloses the contents of the cell. This membrane is probably bimolecular and lipoprotein in character, and similar to that which is thought to invest most animal cells and many of their cytoplasmic organelles. Immediately external to the sarcolemma is a layer about 500 Å thick; this is an extracellular deposition of material of moderate density (the so-called basement membrane[1]) which gradually diminishes in density as it extends from the sarcolemma into extracellular space and merges with the ground substance of the endomysial connective tissue. Because of its extreme thinness, the sarcolemma is difficult to observe in its longitudinal section; on the other hand, its characteristic unit membrane structure can usually be recog-

nized in transverse section and occasional thickenings and invaginations of the sarcolemma are known to occur[1] at certain regions of the cell. However, using thin-section techniques it is not easy to follow the detailed variations in its course over large areas of the cell surface. For structural investigations of this type the surface replication methods, such as the layer-stripping method developed by Reed and Rudall, are probably far more useful, as the various levels exposed in the tissue may be examined over wide areas[2]. Early investigations using the layer-stripping method revealed the sarcolemma as a continuous elastic sheet, capable of accommodating itself to the structures it encloses, since it often bears undulations corresponding to the striations of the myofibrils[3].

Recently in our work on the post-mortem changes in muscle tissue, particularly as they affect the properties of meat as a foodstuff, we have re-examined the sarcolemma-basement membrane system of pig rectus femoris muscle, using such surface replica techniques. In tissue taken immediately after slaughter and before rigor mortis has been allowed to develop, the myofibrils are almost completely covered with the sarcolemma-basement membrane, so that the striations of the myofibrils are mostly obscured (Fig. 1). However, these membranes do not have a uniform appearance, but show a system of regularly spaced bars indicating an intrinsic periodic structure. This indication that the sarcolemma-basement membrane may possess a regular structure is confirmed by the appearances shown by tissue which is examined after rigor. Here the membranes are observed not as continuous structures but as sheets containing holes of various shapes and sizes or as a system of bars arranged in a very definite pattern (see Figs. 2 and 3). Moreover, this pattern seems related to that of the underlying striations of the myofibrils.

These observations suggest that the sarcolemma-basement membrane is a very labile system and one which may change very rapidly after the death of the animal. More significantly, however, it points to some degree of definite interaction between the sarcolemma and the myofibril, in that there seems to be a specialized mode of attachment of the membranes to different parts of the myofibrillar surface. Although the sarcolemma-basement membrane originally invests the whole surface of the adjacent myofibrils, the portions adhering most tenaciously to the myofibrils (since they remain attached during the rigor process) appear to be at regions between the *H* zone and the *Z* line. These are regions where the actin and myosin filaments interdigitate and lock together during contraction. Possibly, therefore, the sarcolemma-basement membrane, in addition to enclosing the myofibrils of the cell, may be a highly dynamic system in the sense that it can take part in, respond to and conceivably initiate changes in the physiological state of the myofibrils. At certain times the membrane could be quite free from the

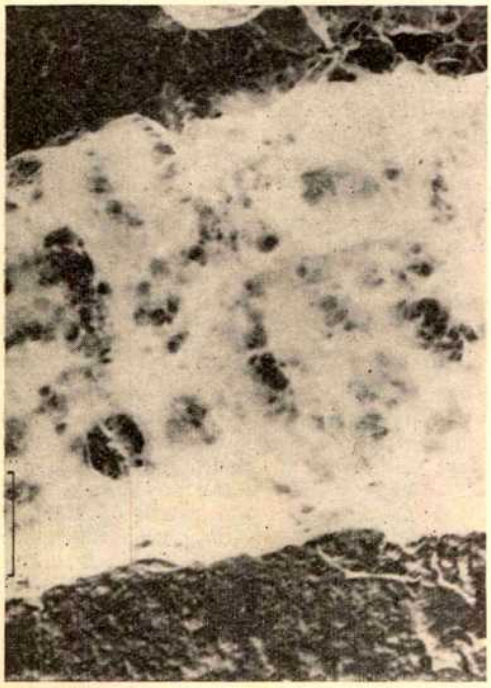

Fig. 1. Surface replica of sarcolemma-basement membrane almost completely covering myofibrils in pre-rigor condition

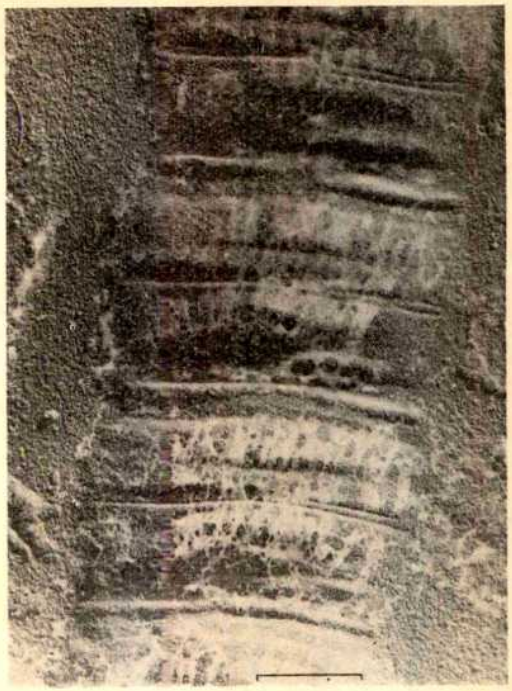

Fig. 2. Surface replica of sarcolemma-basement membrane partially covering myofibrils in post-rigor condition

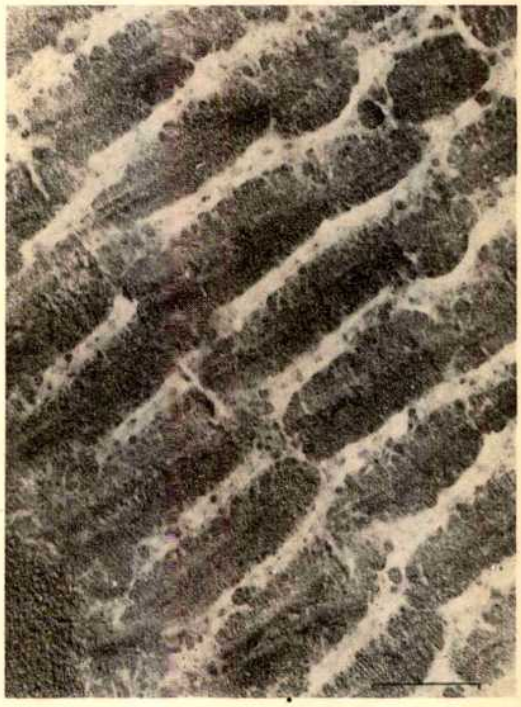

Fig. 3. Surface replica of sarcolemma-basement membrane, with regular arrangement of bars, partially covering myofibrils in post-rigor condition

myofibrils, that is, with no firm links of adherence to the latter. At other times certain regions of the myofibrils could become firmly attached to the sarcolemma. This dynamic view of the sarcolemma forming specialized links with myofibrillar regions could help in assessing its function during the contractile process of living muscle. It could help in understanding how muscle cells act in concert, while it could provide a basis for explaining why regions of the sarcolemma, under electrical stimulation, lead to differing responses in the contractile pattern of the myofibrils[4]. Perhaps most important is the possibility that it could provide a basis for the transmission of the contractile force of the myofibrils to the endomysial and perimysial connective tissue and ultimately to the muscle tendon. Majority opinion at present[5] holds that there is no permanent structural continuity between sarcolemma and the myofibrils, because of the ease with which the sarcolemma may be induced to separate from the muscle substance by a wide variety of methods. What is suggested here is that, depending on the contractile state of myofibrils, a definite pattern of adhesion may occur between the sarcolemma and the myofibrils; further, that this adhesion may be involved not only in transmitting electrical impulses to the myofibrils, but also in transmitting the contractile force of the latter to the connective tissue structures.

Apart from its possible significance in physiological states of muscle, the sarcolemma-basement membrane may play an important part in post-mortem effects, that is, it may determine the rate of release of sarcoplasm and other materials from the muscle cells. Once the integrity of this membrane system has been impaired, it is likely that the endomysial connective tissue will then be concerned in determining the rate of drip or exudation from meat. Work at present in progress in these laboratories, to be reported in full elsewhere, suggests that the drip characteristics of meat depend markedly on whether the tissue is in the pre- or post-rigor condition and therefore on the state of the sarcolemma-basement membrane system.

We wish to acknowledge the support given by the Pig Industries Development Authority during these investigations.

Effect of Peroxides on the Hydration Elongation of Rat Tail Tendon

IT has been shown that physico-chemical changes occur when connective tissue is treated with water that has been subjected to ultrasonic vibrations[1]. The suggestion has been advanced that chemically active substances are formed through the ionization of the water in such ultrasonic fields, and that peroxides are probably involved[2].

Collagen fibres were used to investigate the proposed action of these substances. The fibres were obtained from rat tails (Wistar males, 3 months old) according to the method described by Elden[3]. Before each experiment was carried out, the fibres were dehydrated until a constant ratio of weight and length was achieved. The individual fibres were fixed lengthwise to the bottom of a 2 ml. 'Perspex' cell. The fibres were measured microscopically and divided into three classes according to their diameter. The fixed fibres were set to the mark of a measuring eyepiece (the magnification was × 150). The time was measured from the moment the solution was injected into the cell until the fibre jerked off the setting mark. This time interval served as a measure of the beginning of longitudinal elongation of the fibre due to hydration. Deionized water (*p*H 6·6–6·8) was used as the control solution, while hydrogen peroxide in deionized water at concentrations of 1, 0·1, 0·01 and 0·001 per cent were used as experimental solutions. The concentration of peroxide was controlled by polarography and the solutions were applied at a temperature of 21° C. Table 1 presents the results of our experiments.

Table 1

		I	II	III
	Control	21·40 ± 1·58	27·35 ± 1·97	29·70 ± 1·63
Percentage of hydrogen peroxide	0·001	8·95 ± 0·50	15·40 ± 1·34	20·60 ± 1·89
	0·01	11·90 ± 0·27	13·50 ± 0·64	16·30 ± 0·56
	0·1	13·50 ± 0·71	16·80 ± 0·78	20·10 ± 1·10
	1·0	17·40 ± 0·75	23·40 ± 2·33*	23·61 ± 1·57

Mean time in seconds (± *S.E.*) of the onset of hydration-elongation of the three classes of collagen fibres of various diameter (I, 84–126μ; II, 126–168μ; III, 168–210μ) under the influence of a control solution and various concentrations of hydrogen peroxide. In each group ten fibres were measured. With the exception of one value (*), all the experimental (– peroxide) values are significantly different from the control.

In Table 1 it can be seen that the peroxides influenced the onset of elongation, but that the extent to which they were effective depended on the concentration and diameter of the rat-tail tendon. The beginning of elongation was accelerated most in the fibres with smallest diameter and with the lowest concentration of hydrogen peroxide in the solution; however, in the fibres with larger diameters the maximum acceleration is shifted towards higher concentrations.

These results can be explained in the following way. Either the chemically active substances, formed through the decomposition of hydrogen peroxide, facilitate the penetration of water through the membrane enveloping the rat-tail tendon[4], or they directly influence the hydration rate of the collagen proteins[5]. Of special interest is the decrease in the efficiency of peroxides with increasing concentrations, which is analogous to the haemolytic effect of peroxides[6]; however, for the time being, this effect must remain unexplained.

A Re-investigation of the Effects of 'Nilevar' on the Right Gonad of the Pullet

IN the female chicken, as in most female birds, only the left gonad develops into a functional ovary. Surgical removal of this left ovary is followed by hypertrophy of the right rudimentary gonad, indicating that the ovary exerts an inhibitory effect on the development of the right gonad (see refs. 1 and 2 for reviews). Kornfeld[3] and Taber *et al.*[4,5] demonstrated that physiological amounts of oestrogen inhibit the hypertrophy of the rudimentary gonad following sinistral ovariectomy. This inhibition does not appear to be due to suppression of pituitary gonadotrophins.

Kornfeld[6] administered 'Nilevar' (17α-ethyl-19-nortestosterone), a synthetic progestational compound and a reported "anti-oestrogen", to intact pullets. He reported a four-fold increase in the weights of the rudimentary

right gonads and interpreted this hypertrophy as due to the anti-oestrogenic effects of the drug, releasing the rudimentary gonad from the inhibition of endogenous oestrogens.

Our experiments with ovariectomized birds[7] have provided evidence to support the hypothesis that the avian ovary produces another, non-oestrogenic substance which also inhibits the development of the rudimentary gonad. If our hypothesis is correct, the right gonad of a pullet treated with 'Nilevar' should remain inhibited if 'Nilevar' is acting only as an anti-oestrogen. For this reason, it was decided to re-investigate the effects of 'Nilevar' on the rudimentary right gonad of the chicken.

(*A*) *Normal pullets.* Twenty-three 60-day-old intact brown Leghorn pullets received subcutaneous injections of 3·0 mg of 'Nilevar' (dissolved in olive oil and 5 per cent benzyl alcohol) each day for 40 days; eighteen pullets of identical age served as controls and received only the vehicle of the drug. New feathers of both groups were feminine, providing evidence of circulating oestrogens and indicating that 'Nilevar' had no anti-oestrogenic effect at the feather target organ. The combs and wattles of the birds treated with 'Nilevar' were stimulated and, at the time of autopsy, the combs were more than four times the size of those of the controls (height × length = 54·7 cm^2 as compared with 12·6 cm^2). In addition, the treated pullets were more aggressive and occasionally crowed. These observations are evidence for the androgenic action of 'Nilevar'.

At the time of autopsy, control pullets revealed no grossly visible right gonadal tissue, whereas hypertrophied tissue was observed at the site of the right gonad in each experimental bird. However, when tissues from control and treated birds were examined histologically, it was found that the right gonads of both groups were inhibited and were indistinguishable from each other. The hypertrophied tissue which had been observed grossly in pullets treated with 'Nilevar' consisted of enlarged Wolffian bodies. These were estimated to be from three to four times the size of those in controls and the tubules were markedly larger and hyperplastic.

(*B*) *Sinistrally ovariectomized pullets* (*poulards*). Twenty-four pullets were ovariectomized at the age of 21 days and eighteen of these received 0·4 mg of 'Nilevar' per 100 g body-weight beginning the day of operation and continuing for 8 weeks. Again, the combs of the birds receiving 'Nilevar' were greatly stimulated (57·0 cm^2 as compared with 19·5 cm^2, at the time of autopsy).

At the time of autopsy, the right gonads of untreated poulards were hypertrophied and averaged 85·8 mg. The average weight of the gonads from poulards treated with 'Nilevar' was 53·9 mg, which does not differ significantly from that of controls. However, because the weights of the tissue from the experimental group include the greatly enlarged Wolffian bodies, it is a reasonable assumption that treatment with 'Nilevar' produced a significant retardation in the development of the right gonad.

Histologically, the gonads of poulards treated with 'Nilevar' showed considerable variability. In some, the general structure was similar to that of the inhibited right gonad of pullets although some proliferation of medullary tissue had occurred. The larger gonads were less well differentiated, but otherwise resembled those of untreated poulards.

These experiments failed to demonstrate any anti-oestrogenic effect of 'Nilevar' and the right gonads of treated pullets were inhibited to the same degree as those of untreated controls.

The right gonads of poulards treated with 'Nilevar' were retarded in size and degree of differentiation when compared with those of controls. Undoubtedly, this resulted from the androgenicity of 'Nilevar', which even on a conservative estimate must be about one-sixteenth as potent as testosterone propionate[8]. On the basis of this estimate, our poulards received the equivalent of 25 μg of testosterone propionate daily, a dosage known to inhibit or retard the growth of the right gonad in poulards[5].

Evidence for the androgenicity of 'Nilevar' (comb stimulation and the hypertrophy of the androgen-sensitive Wolffian body) was observed in both intact pullets and poulards. Kornfeld[6], basing his conclusions entirely on gross observations, reported hypertrophied right gonads in pullets treated with 'Nilevar'. Our observations show that the hypertrophied tissue observed by us and probably by Kornfeld was due to the hypertrophy of the Wolffian body and not to the hypertrophy of right gonadal tissue.

Plurivesicular Nerve Endings in the Pulmonary Artery

PREVIOUS electron microscopic studies of blood vessels have failed to reveal "nerve endings" or synaptic regions within the muscularis[1–4] although small bundles of myelinated and unmyelinated axons have been clearly seen in the adventitia. The specific histological fluorescence method of Falck and Hillarp[5] for catecholamines has provided morphological evidence for the intraneuronal, varicose distribution of the adrenergic transmitter in blood vessels[6]. While electron microscopic details are available on the terminal autonomic innervation of non-vascular smooth muscle[7–10], the identification of comparable neuro-effector relationships in blood vessels is lacking, apart from the preliminary observations of de Robertis and de Iraldi[11].

In recent light microscopic observations of the isolated pulmonary artery-nerve preparation, in which there is direct, unequivocal evidence for postganglionic sympathetic vasoconstrictor innervation of the vascular smooth muscle[12], Verity *et al.*[13] demonstrated the existence of an unmyelinated nerve plexus of small diameter located primarily in the adventitio-medial zone of the artery.

In view of the unequivocal pharmacological and physiological evidence for the existence of a motor system in this vessel, we attempted to identify the adrenergic transmitter termina.

Pieces of tissue from the region of the bifurcation of the pulmonary artery were rapidly excised from cats previously anaesthetized with sodium pentobarbital. The tissue was washed in cold, phosphate buffered 3 per cent glutaraldehyde and prefixed for 1 h. Subsequent fixation was carried out in phosphate buffered 2 per cent osmium tetroxide[14] for 2 h, followed by dehydration in ice-cold ethanol and embedding in 'Epon 812'. Sections were double stained with uranyl acetate and lead citrate and examined with a Hitachi *HU*-11 electron microscope.

No axon-like profiles or synaptic regions were identified within the inner muscularis after examination of many grid squares, representative of twenty-eight 'Epon'-embedded blocks. In general, the structure and arrangement of the smooth musculature was similar to that of the aorta[15,16], and will not be considered further here.

Winding, varicose, unmyelinated axons of 0·2–0·5μ diameter were identified with some difficulty, presumably because of their low distribution density, in the adventitio-medial junction, and outer smooth muscle-elastic lamellae of the muscularis. Typical neurotubules were identified in the axoplasm[17,18]. Vesicle-containing "synaptic nerve endings" were noted in many preterminal axons. The predominant vesicular population was granular and composed of Type 1 and Type 3 vesicles (after Grillo and Palay[19]) with diameters of about 1000 Å and 450 Å respectively (Fig. 1). While typical agranular synaptic vesicles were occasionally observed, they never accounted for more than 15 per cent of the vesicular population in any one ending, and in many instances were considered to represent inadequately stained Type 3 structures. Longitudinal fragments of the neurotubular system, 75 Å in diameter, were present in some vesicular regions, accompanied by mitochondria and elongate granular (Type 1) and agranular vesicles (Fig. 2). The plasma membranes of smooth muscle cells were never in close proximity to the nodose axon expansions.

The identification of a plurivesicular "synaptic nerve ending" in the adventitio-medial zone of the pulmonary artery provides confirmatory evidence for the presence of an adrenergic neuroeffector system, previously suspected from *in vitro* pharmacological observations[12,13]. A plurivesicular component has been recognized in what are presumed to be adrenergic nerve endings innervating the pineal gland, in fine branches of the splenic nerve penetrating the adventitia of splenic blood vessels[11] and in the anterior hypothalamus of the rat[20]. Evidence for the association of granular vesicles with catecholamines is very strong. The plurivesicular endings of this study are unusual in containing a large number of granular (1000 Å in diameter) vesicles with very few synaptic (presumed cholinergic) vesicles. The mixed, heterogeneous nature of the granular vesicular population allows for the use of the term "plurivesicular", as coined by de Robertis and Pellegrino de Iraldi[11], but the relative lack of agranular vesicles is in marked contrast to their observations on the adrenergic axons and endings in the pineal gland and splenic nerve. Also of note was the complete lack of a junctional relationship between the adrenergic nerve endings and the smooth muscle membranes.

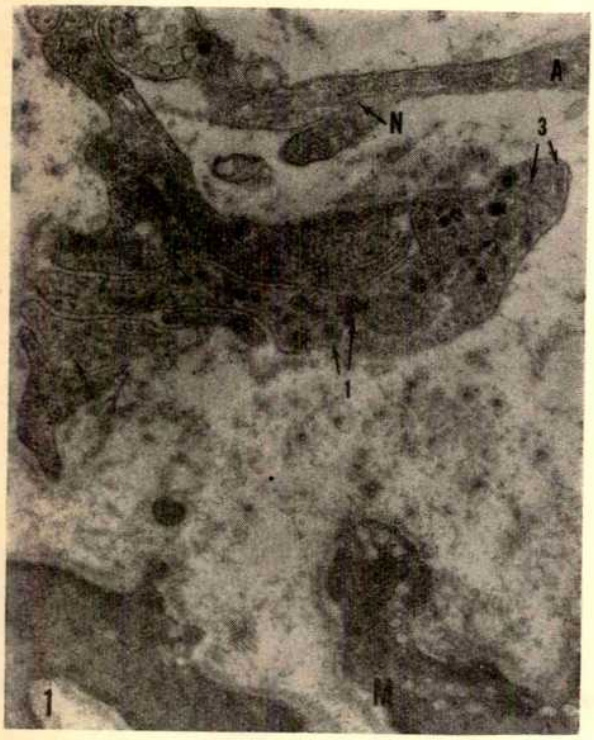

Fig. 1. Granular and agranular vesicle-containing axonic expansion in the medio-adventitial zone of the pulmonary artery of the cat. Large (~1000 Å diameter) light and dense osmiophilic granular vesicles surrounded by unit limiting membrane (Type 1) are interspersed with smaller granular vesicles (Type 3) with light osmiophilic cores. *A*, Adjacent, small-diametered axon with neurotubules (*N*). *M*, Smooth muscle. (×*c.* 21,000)

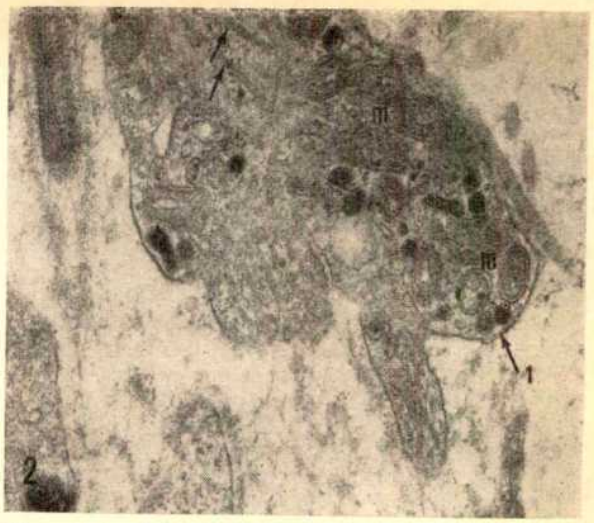

Fig. 2. Preterminal vesicle-containing structure with numerous mitochondria (*m*). Neurotubules (arrows) approach the vesicle aggregation, some of which appear elongate. (×*c.* 33,750)

PHARMACOLOGY

A New Class of Orally Effective Antifertility Agents with Hypocholesteraemic Activity

THIS communication describes the synthesis and some of the relevant pharmacological properties of a typical member (I) of a new class of agents with potent antifertility and hypocholesteraemic effects in experimental animals.

(I)

1-[2-[*p*-[α-(*p*-Methoxyphenyl)-β-nitrostyryl]-phenoxy] ethyl]pyrrolidine.

A convenient synthesis of I from commercially available starting materials is illustrated by the following sequence of reactions: (*A*) Treatment of a mixture of β-bromophenetole and anisic acid with polyphosphoric acid at 80° C gave a 97 per cent yield of crude *p*-(β-bromoethoxy)-*p'*-methoxybenzophenone (II) (melting point of 111·5°–113° (from methanol)). Analysis calculated for $C_{16}H_{15}BrO_3$: carbon, 57·33; hydrogen, 4·51; bromine, 23·84. Found: carbon, 57·28; hydrogen, 4·43; bromine, 23·57. (*B*) Treatment of II with excess pyrrolidine for 4 h in a refluxing solution of tetrahydrofuran gave, after recrystallization of the crude product from aqueous methanol, an 87·5 per cent yield of pure *p*-methoxy-*p'*-[β-(1-pyrrolidinyl)ethoxy]benzophenone (III) (melting point 97°–98·5° C). Analysis calculated for $C_{20}H_{23}NO_3$: carbon, 73·82; hydrogen, 7·12; nitrogen, 4·31. Found: carbon, 73·95; hydrogen, 7·28; nitrogen, 4·18. (*C*) Reaction of III with the benzyl Grignard reagent gave a 78–86 per cent yield of 1-(*p*-methoxyphenyl)-2-phenyl-1-(*p*-[β-(1-pyrrolidinyl)ethoxy]phenyl)-ethanol (IV) (melting point 121°–122° C) from *cyclo*hexane-ethyl acetate. Analysis calculated for $C_{27}H_{31}NO_3$: carbon, 77·66; hydrogen, 7·48; nitrogen, 3·36. Found: carbon, 77·61; hydrogen, 7·42; nitrogen, 3·35. (*D*) Conversion of IV to I (free base) was effected in yields of 75–79 per cent by treating IV in glacial acetic acid with 2 equivalents of 90 per cent nitric acid at 25°–30° C for 1·5–2·0 h. Recrystallization of the resulting crude product from methanol gave pure I, despite the characteristically indefinite melting point; 103°–106° C (softens) 120° C (liquid phase). Analysis calculated for $C_{27}H_{28}N_2O_4$: carbon, 72·95; hydrogen, 6·35; nitrogen, 6·30. Found: carbon, 73·15; hydrogen, 6·16; nitrogen, 6·27. The ultra-violet spectrum obtained in methanol was λ_{max} (mμ), 282, 239; $E^{1\%}_{1cm}$, 348, 485. The nuclear magnetic resonance spectrum of this material showed it to be essentially a 50 : 50 mixture of two isomers. Separation of the isomers resulted by recrystallization from methanol: isomer *A*, melting point 136°–138° C, nuclear magnetic resonance methoxy hydrogen at 3·75 δ; isomer *B*, melting point 117°–119° C, nuclear magnetic resonance methoxy hydrogen at 3·70 δ. Optical crystallographic studies showed that I-*A* is orthorhombic and isomer I-*B* monoclinic. The variability in melting range of I may thus be attributed in part to the presence of two crystalline modifications, as well as to possible variability in isomeric composition. Both isomers possess identical hypocholesteraemic and antifertility activity. All the pharm[illegible] cological data that follow refer to the mo[illegible] of the 50 : 50 isomer mixture. This [illegible] prepared by mixing warm acetone [illegible] anhydrous citric acid (5 per ce[illegible] crystalline I citrate that s[illegible]

suspension in 4 per cent aqueous acacia once daily for 7 days by oral intubation led to plasma total cholesterol depressions of 26–52 per cent relative to the response of an equal number of control animals.

Another controlled experiment in rats, in which I citrate was incorporated in the diet at doses of 0·5 mg/kg to 10 mg/kg, gave 55–67 per cent plasma total-cholesterol depressions at the end of a 104-day treatment period. Analysis of the liver sterol pattern in the 104-day treated animals by the method of Rodney *et al.*[1], with particular attention being paid to desmosterol (24-dehydrocholesterol), showed that I is without significant effect on the sterol synthetic sequence in that organ.

Administration of I citrate (60 mg/kg/day) by oral intubation to one male and two female monkeys produced, by the end of the 90-day period of treatment, plasma cholesterol depressions of 44–50 per cent relative to the pre-treatment control values. Oral treatment of one male and two female dogs with I citrate (20 mg/kg/day) for the same period produced depressions of 27–60 per cent, also relative to pre-treatment control-levels. Doses of this size in the monkey and dog exerted a slight (monkey) to moderate (dog) desmosterogenic effect on the liver sterol synthetic sequence in these species: in partial compensation, however, the plasma cholesterol depression produced by I in the monkey was accompanied by a parallel depression of all plasma sterols, so the net effect was not simply a shift in the desmosterol/cholesterol ratio.

Species in which the antifertility activity of I has been demonstrated include the mouse, the rat, and the dog. In the prophylactic mouse test, a fertile male was introduced to mature female mice in groups of four who were being fed the drug continuously in a diet of ground grains and powdered milk. After 2 weeks, the male was withdrawn and the females were carried to term. The minimal effective dose for complete protection (ED_{100}) was about 50 μg/kg/day. In the post-coital mouse test, the drug, suspended in 0·25 per cent methylcarboxycellulose, was administered in a single dose by gavage to females previously caged with a fertile male for 72 h. A single dose of about 500 μg/kg was required to prevent pregnancy.

In the rat, day 1 of pregnancy was established by the identification of sperm in the vaginal smear. On day 8, the females were killed and the uteri examined for implantation sites. Administration of compound I orally by gavage at 25 μg/kg daily was 100 per cent effective in inhibiting implantation. A single oral dose of 500 μg/kg on post-insemination day 1, 2 or 3 was equally effective. The $E.D._{100}$ of I in the dog lies between 250 and 500 μg/kg/day when given orally by capsule continuously for 15 days beginning on the day of the first of three alternate-day matings. The compound caused a weak uterotrophic response in the rat, but when given concomitantly with oestradiol, an anti-oestrogenic effect was observed.

Acute toxicity studies of I gave an oral $L.D._{50}$ of 832 ± 32 mg/kg in the mouse and 1,778 ± 53 mg/kg in the rat. [illegible] tolerate chronic doses in the diet exceeding one [illegible] es the therapeutic levels [illegible] $_{100}$ values in the rat [illegible] c and anti-oestro- [illegible] for his crystallo- [illegible] d his staff [illegible] for their

Role of Catecholamines in the Amphetamine Excitatory Response

WHETHER amphetamine exerts its behavioural excitatory action in the brain directly or indirectly by interference or synergism with the catecholamines (noradrenaline and dopamine) is open to debate[1,2]. The advent of α-methyl *para*-tyrosine[3] (α-MPT), which inhibits the *in vivo* synthesis of 3,4-dihydroxyphenylalanine (DOPA)—the physiological precursor of the catecholamines—offers a new way of investigating this problem.

Spector *et al.*[3] showed that after treatment with α-MPT the content of noradrenaline in the brain and other organs gradually decreased, and after repeated doses it finally became impossible to detect noradrenaline. We found, using twelve rats, that even 3–5 h after one dose of α-MPT (75–200 mg/kg subcutaneously), amphetamine (3 mg/kg subcutaneously—referring to the *d*-amphetamine base) elicited little motor activity. The rats sat quietly and performed some grooming actions; with the lower doses, however, they also walked forwards. After repeated doses of α-MPT, even 6 mg of amphetamine/kg given subcutaneously was antagonized (Table 1).

Table 1. BEHAVIOURAL EFFECTS OF AMPHETAMINE AND *l*-DOPA IN RATS PRETREATED WITH REPEATED DOSES OF α-METHYL *para*TYROSINE

All rats received subcutaneously 100 mg/kg α-MPT 9, 6 and 3 h before treatment with amphetamine and DOPA

	Dose (mg/kg s.c.)	No. of rats	No. of rats showing stereotype behaviour*	Level of motor activity
Amphetamine	6	6	0/6	Low†
Amphetamine + *l*-DOPA	3 200	6	6/6	High‡
l-DOPA	400	6	0/6	Low§

* Constant sniffing, licking or biting of cage netting wire.

† Sat quietly most of the time. Performed some grooming and 50–70 min after amphetamine walked forward a little. Very little sniffing.

‡ Vigorous sniffing and biting for more than 30 min, walked forwards, backwards and circled about, but no grooming.

§ Sat or lay quietly, grooming, very little sniffing.

Amphetamine, when given alone, always produced marked hyperactivity and continuous, stereotype sniffing, licking or biting of the wire netting of the cage[2,4,5] (more than 200 rats were observed when doses of 1·5–30 mg/kg were given subcutaneously). With doses larger than 3 mg/kg, forward walking was completely abolished for a while; the rats performed their stereotype activity without moving, or they only walked backwards[4,5]. Grooming actions were not observed[5].

The experimental results in Table 1 strongly suggest that the antagonistic effect of α-MPT on amphetamine is due to the inhibition of DOPA-synthesis and not to some other action of the drug. Doses of up to 400 mg *l*-DOPA/kg given subcutaneously (nine rats treated) also had little effect on the gross behaviour of rats which had not received any pretreatment. A larger dose of *l*-DOPA (1,200 mg/kg given subcutaneously), however, produced hyperactivity and stereotype behaviour similar to that seen after amphetamine (ten rats)[6].

As inhibition of amphetamine induced behaviour would s[uggest] neuroleptic drugs[5], [the] activity. Here [it] perphenazi[ne] type a[ction] [7–10] days after the implantation of [p]eriod was considered suitable for the [im]portant degree of tolerance to and [al]kaloid[2]. Doses ranging [us]ed (Table 1). 3–4 min

We thank Merck, Sharp and Dohme for a generous supply of α-MPT.

Intraventricular Administration of Nalorphine to Mice implanted with Pellets of Morphine

WHENEVER nalorphine is administered to white mice implanted with a pellet of morphine (base) an 'abstinence syndrome' is produced[1]. Its well-defined symptomatology and characteristics have been reported elsewhere[2–4]; the action of several drugs on the abstinence syndrome has also been tested[5–7]. However, its genesis is still not well understood. Because of this, it was thought of interest to determine whether nalorphine injected by the intraventricular route can elicit the abstinence syndrome in tolerant mice.

Male and female white mice weighing 25–30 g were divided into several groups of five animals each. Some groups were used as controls, while a morphine pellet was implanted in each mouse of the other groups; the daily absorption ranged between 90 and 130 mg/kg (ref. 1). Drugs were dissolved in physiological saline and administered in volumes of 0·025 ml. Intraventricular injections were performed according to the method of Haley and McCormick[8] as modified by Adler[9]. The correct location of the injected material was confirmed by (1) histological investigation after administration of indian ink; (2) by the appearance of the signs observed by Haley and McCormick immediately after a simple ventricular puncture or after the administration of saline and drugs (stupor, changes in the tail position, hyperexcitability and even slight convulsions)[8]. Observation of the mice was discontinued 15–20 min after the intraventricular injection.

In control mice, intraventricular injection of nalorphine (25 and 50 μg/kg) produced immobility or hypomotility during the first 5 min, followed by the appearance of exophthalmus, catatonia, and restlessness alternating with normal behaviour. The higher the dose, the more accentuated were the symptoms. Larger quantities (100 μg/kg) induced depression. Intraventricular injection of morphine (50 μg/kg) induced immobility in control mice; after 10 min some tail rigidity and restlessness were observed. Doses of 500 μg/kg elicited convulsions [fo]llowed by a typical morphine syndrome.

ml., results were obtained comparable with those for similar doses in more dilute solution, but recovery began sooner. In any event, two points must be emphasized: (*a*) an intense abstinence syndrome was never observed; and (*b*) the weak abstinence syndrome presented by some groups always appeared with a delay of 10–15 min (Table 1).

(1) In this series doses were administered dissolved in 0·025 ml. of physiological saline
(2), (3) and (4), see text.

The results reported here are in striking contrast with those obtained when nalorphine was administered intraperitoneally in mice implanted with morphine. In such cases, the manifestations of the abstinence syndrome were induced approximately 2 min after the administration of the drug; 3 min later, the symptoms increased significantly and in less than 10 min the abstinence syndrome actually reached a maximal intensity[1,2]. In order to exclude the possibility that the abstinence syndrome might be masked or hindered by the intraventricular injection of nalorphine, experiments were performed on various groups of mice: (*a*) 20 min after the intraventricular injection of nalorphine, 10 mg/kg of the drug was given intraperitoneally to all the animals in the groups shown in Table 1. Typical and intense abstinence symptoms appeared swiftly after the intraperitoneal injection, or the existing weak signs were intensified. (*b*) An intraventricular injection of saline was administered and immediately afterwards mice received a dose of nalorphine (10 mg/kg) intraperitoneally. (*c*) Nalorphine was injected intraperitoneally first, and saline was then injected intraventricularly. In the last two groups, a typical and intense abstinence syndrome could be seen after the symptoms that characterize the intraventricular injection.

Lockett and Davis[10] have shown that nalorphine given intracisternally is much less effective in antagonizing morphine than when it is administered via the systemic route. Nevertheless, the absence of precocious and definite symptoms of abstinence in the experiment reported here, even with high doses of nalorphine, was astonishing. These results may be interpreted as evidence that nalorphine itself is not the compound responsible for the production of the abstinence syndrome in mice that have received morphine chronically. The compound would trigger the abstinence syndrome if an 'activation process' were to occur. The 'active compound' may be derived from the injected nalorphine, from the morphine previously deposited in the animal or from some product that results from the chronic administration of morphine. This activation process (or processes) would take place slowly or incompletely in the central nervous system; for this reason, no abstinence syndrome or a delayed and weak abstinence syndrome is observed when nalorphine is injected into the ventricles. On the other hand, the 'activation process' may be fulfilled outside the nervous tissue; thus, when nalorphine passes into the systemic circulation, the 'active molecule' is set free and reaches the central nervous system to induce the abstinence syndrome. These possibilities are not opposed; on the contrary, they may enhance each other.

VIROLOGY

Heterogeneity of Rabbit Serum Interferons

THERE is evidence that, in the rabbit, virus-induced interferon (VII) is induced differently from endotoxin-induced interferon (EII). The induction of VII is inhibited by actinomycin *D* (ref. 1) and by puromycin[2], while the induction of EII is not. Furthermore, Hallum *et al.*[3] demonstrated that, in the mouse, the molecular weight of EII is greater than that of VII. In view of these differences between EII and VII, we decided to study the molecular sizes of rabbit serum interferons induced by virus and by endotoxin.

VII was produced by injecting 5×10^9 P.F.U. of Herts strain Newcastle disease virus (NDV) intravenously into albino rabbits weighing, on average, 3 lb. and collecting serum after 7 h (ref. 4). EII was obtained from serum 2 h after an intravenous injection of 20 μg of *E. coli* endotoxin prepared according to the Boivin method[5].

The molecular sizes of VII and EII were compared by the gel-filtration method, as already described[6]. In brief, samples with phenol red incorporated as an internal standard were overlayed on a 'Sephadex *G*-100' column, then eluted with a phosphate buffered saline of *p*H 6·5. Fractions of constant volume were collected. The absorbancy of each fraction was determined spectrophotometrically at 280 mμ wave-length. Interferon activity was measured by the reduction of vesicular stomatitis virus (VSV) plaques in rabbit embryo cell cultures.

A typical set of results for VII and EII is presented in Figs. 1 and 2. As may be observed from Fig. 1, two major protein peaks were evident: one at fraction 18, the exclusion point of this column, the other at fraction 26·5, presumably globulin and albumin portions of the rabbit serum, respectively. Phenol red peaked at fraction 59·5.

Some phenol red was found to bind with albumin and post-albumin proteins which peaked at fraction 26·5 (coincidental with the 280 mμ peak), thus forming a convenient visual internal standard.

The interferon activity curve also showed two peaks, one being at the exclusion point, the other at fraction 29. Afterwards, fractions 14–22 were pooled, as were fractions 23–37. Interferon assays of these pools showed that about 32 per cent and 68 per cent of the total activity was associated with the heavy and light peaks, respectively. Repeated chromatography of VII produced by different individual rabbits showed that these peak positions were reproducible. Only the ratio of interferon activities distributed in the heavy and light peaks varied somewhat from sample to sample.

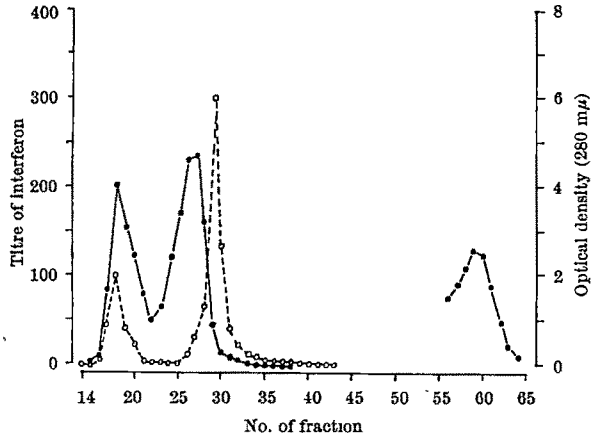

Fig. 1. Fractionation of VII on 'Sephadex G-100' column. O - - - - O, Titre of interferon, ●——●, O D (280 mμ)

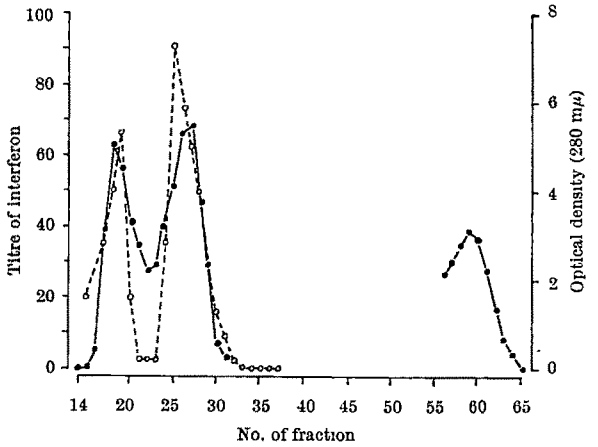

Fig. 2. Fractionation of EII on 'Sephadex G-100' column. O - - - O, Titre of interferon, ●——●, O.D (280 mμ)

The results concerning EII (Fig. 2) showed peak positions similar to those referring to VII, with the exception that the second interferon peak was at fraction 25·0. Interferon assays of the pooled peaks indicated that approximately 36 per cent and 64 per cent of the total activity were associated with the heavy and light peaks, respectively. Repeated chromatography of EII produced by different individual rabbits also showed reproducible peak positions, varying only in the ratio of interferon activity distributed in the heavy and light peaks.

When the lighter peaks of both VII and EII were separately pressure dialysed, and the concentrated materials afterwards mixed with normal rabbit serum, then re-chromatographed on the 'Sephadex G-100', no change of peak positions was observed.

Because both heavier species of the interferons peaked at the exclusion point of the column, they were roughly estimated to have molecular weights of more than 100,000[7]. The lighter species of VII was estimated to have a molecular weight of 40,000, whereas that of EII was 56,000[6].

The dual peak phenomenon observed here suggests that in the case of rabbit VII and EII, there are at least two molecular species of interferons.

This molecular heterogeneity of rabbit VII and EII is strikingly different from results obtained in mice[3]. It is probably unlikely that the heavier species represents a simple reversible binding of the lighter species to the heavier proteins of the serum as no such binding was found when the lighter species was incubated with normal rabbit serum. One possible explanation of these results is that the incubation of either virus or endotoxin triggers off more than one interferon-inducing mechanism each responsible for the production of a different molecular species; however, the predominant mechanism may vary.

A Simplified Course of Immunization for the Antirabies One-day-egg Vaccine

ANTIRABIES vaccine produced from animal brains has been known to contain an encephalitogenic factor[1]. Attempts have been made, therefore, to remove this factor from brain tissue vaccines by physicochemical means[2–4], or to prepare vaccines from the brains of newborn animals[5–7], tissue cultures[8,9] or embryonated eggs[10,11]. Among these attempts, the use of chick embryos has incurred the difficulty of obtaining only a low virus yield in the embryo. However, it was discovered in our laboratory that the viral yield in the chick embryo markedly varied, depending on the strain of virus[12], its grade of adaptation to eggs[12] and the age of eggs inoculated[13]. Eventually we were able to adapt the rabbit-fixed Nishigahara strain of rabies virus to the 1-day-old chick embryo to such an extent that the resulting strain (named '*NOPM*') was able to yield a high concentration of virus in the embryo when inoculated into 1-day-old eggs[12]. A beta-propiolactone-inactivated vaccine prepared from this stimulated a good antibody response among volunteers who received it intradermally in 3–4 doses of 0·1 ml. spaced at 3–7 day intervals[14].

The next question to be solved was whether this course of injection could be simplified without lowering the efficacy of this vaccine so as to make feasible a mass prophylaxy against rabies in a population facing the possible risk of being bitten by rabid animals. Thus, in an attempt to determine the simplest schedule for this vaccine to confer a satisfactory immunity, we undertook to vaccinate two groups of persons in different schedules. The volunteers were students of the Yokohama City University School of Medicine who had never previously received antirabies immunization. The vaccine was prepared by the standard method described earlier[14]; its potency as expressed by the Habel index[15] was 4,900, and its nitrogen content was 520 γ/ml. One group of volunteers received only one intradermal dose of 0·1 ml., while the other group received the same injection twice with a one-week interval. Bleeding was effected just before and 1, 2, 4 and 6 weeks after the first immunization, and the test for neutralizing antibody was performed using mice in the manner recommended by the World Health Organization[16].

As indicated in Table 1, the one-dose group showed weak antibody responses, and only four of sixteen subjects developed appreciable levels of antibody, which averaged about 1 : 10. In contrast, in the two-dose group, ten of sixteen volunteers developed antibody higher than 1 : 10,

and there was only one person who showed no antibody rise at all. Systemic reactions among these volunteers were not appreciable except in some of the two-dose group volunteers who complained of swelling and pain of the axillar lymph node following the second injection; however, this condition disappeared within a couple of days, and in none of them was a rise in body temperature observed to more than 37° C. As to local reactions, erythema averaging 1·1 cm in diameter was seen at the injection site after the first immunization, and in the two-dose group the second injection caused erythema and induration measuring on the average 3·7 and 2·0 cm, respectively, on the next day, but all these reactions disappeared within a week.

Another experiment was then undertaken to determine the effect of one-dose injection as a booster for eighteen persons, who had volunteered in the previous experiment carried out 21 months before in which the vaccine was given in three to four doses[14]. As controls, twenty-five new volunteers, who had not experienced any previous antirabies vaccination, were given one intradermal injection of the same vaccine simultaneously in an equal amount of 0·1 ml. The vaccine used showed a Habel index of 4,100, and contained 470 γ/ml. of nitrogen. As can be seen from Table 2, it was again found that the one-dose injection was insufficient to stimulate an antibody rise in the group of primary immunization, but the same dose of vaccine was enough to elevate the antibody levels in the booster group. In the latter group, fairly high levels of antibody were reached within one week, and in most of the subjects the maximum levels were about equal to those reached previously in their primary vaccination. The systemic and local reactions were similar to those in the primary vaccination group. Such a response is comparable with that usually obtained with the classical brain-type vaccine, and therefore the *NOPM* one-day egg vaccine can be used for mass prophylaxy of a population against rabies. The most satisfactory results will be obtained by the two-dose immunization as the primary course and giving one booster dose after every 2 years.

BIOLOGY

A Specific Midventral Gland in Gerbils

MAMMALIAN skin is rich in specific glands which perform various functions. Dambach[1] found a specific midventral gland in *Meriones unguiculatus* and gave a histological description of it. Other references exist in which attention is directed to the presence of such a gland in *Rhombomys opimus*[2]; however, its structure was not studied. The presence of similar glands in other gerbil species also remained uncertain, and thus we endeavoured to bridge this gap. Unfortunately, these glands cannot be distinguished in dry (museum) preparations, so that either living or alcohol and formalin-fixed animals were required. (Part of the material was placed at our disposal by the Zoological Museums of the Zoological Institute of the U.S.S.R. Academy of Sciences and of the University of Moscow, and by Mr. V. S. Lobachev (University of Moscow), whom we thank.)

As can be seen from Tables 1 and 2, the midventral gland was found in almost all the males inspected and also in many females; furthermore, the gland occurs in both adult and young animals (a well-developed gland was found in a 23-day-old male).

The gland is situated on the mid-line of the body, almost in the middle of the abdomen. In appearance it is a small thickening of the skin—two to three times greater than neighbouring areas (Table 3), and many ducts empty into this region (in *Rhombomys opimus* there are from forty to sixty-seven). The glandular field is irregularly oval, and elongated along the mid-line of the abdomen. The dimensions of the gland are presented in Table 2 (measurements were made from the internal surface of the skin).

As can be seen from Table 2, the glands in males are larger than those in females. It is of interest here that in *Rhombomys opimus*—the species of larger animals compared with other species—it turned out that the glands were even smaller than those in other gerbil species.

The midventral gland can easily be distinguished from the outside as the hair in the region is much shorter and, together with the surrounding hair, a dirty-white colour. When pressed, a dense white secretion with an odour of burnt horn exudes from the ducts.

A histological investigation of the midventral gland was undertaken. The gland was embedded in celloidin and cut along its longitudinal axis. Sections were stained with haematoxylin-eosin. Histologically, the structure of the gland was the same in all species of gerbils studied: the gland is formed by a complex of closely adjoining complicated alveolar glands with a holocrine type of secretion. The glands are considerably larger (in *Rhombomys opimus*: 0·38 × 1·10; 0·27 × 1·21; 0·88 × 3·41; 0·71 × 1·87 mm) than normal sebaceous glands in the hair sacs (in *Rhombomys opimus* the size of sebaceous glands is: 17 × 28, 46 × 52μ). (It is probable that the glands of the midventral glandular field developed from normal sebaceous glands.) The lobes of an individual gland (the size of these lobes differing widely) empty into a common duct which is widened at its base and which serves as some sort of reservoir for the secretion. In its upper regions, the duct narrows and empties into a small orifice at the surface of the skin. Each duct is situated laterally from the hair sac, but the size of the large duct and that of the tiny hair are so disproportionate that it is impossible to say whether or not the ducts empty into the hair sacs. It would be better to consider that the hair sac is an appendage of the duct.

The epidermis and its corneous layer in the region of the glandular field attain a somewhat greater thickness than in adjoining areas (Table 3).

The reticulate layer of the dermis in the region of the glandular field has in general a structure similar to normal skin, although it tends to be somewhat thinner (Table 3). The papillary layer formed by almost continuous aggregation of sebaceous glands is much thicker in the region of the glandular field than in normal skin.

The presence of the midventral gland enables us to suggest a new systematic character for the representatives of the sub-family Gerbillinae. However, a midventral gland resembling that of gerbils in its structure is also found in other animals systematically very remote from the gerbils (*Blarina, Neotoma, Cricetus, Peromyscus, Cricetulus, Masocricetus, Phodopus, Sigmodon, Martes zibellina, Rattus exulans*[3–8]). This finding indicates a convergence in the evolution of these glandular formations in various mammalian species. This character should therefore be applied with care in any elucidation of the relationship between such mammals—as was pointed out by Quay and Tomich[8].

Table 1. GERBIL SPECIES INVESTIGATED AND NUMBER OF ANIMALS WITH THE MIDVENTRAL GLAND

Species	No of animals inspected		No. of animals with the midventral gland	
	Males	Females	Males	Females
Meriones tristrami	4	6	4	2
M. persicus	3	2	1	1
M. meridianus	11	14	11	13
M. erythrourus	4	4	2	1
M. tamariscinus	2	2	2	2
M. unguiculatus	1	1	1	1
Rhombomys opimus	20	9	20	6

Table 2. DIMENSIONS OF THE MIDVENTRAL GLAND (IN MM)

Species	Sex	No. of gerbils inspected	Dimensions of the gland	
			Length	Width
Meriones erythrourus	♂	4	21–33; *M* 29	6–7, *M* 7
	♀	1	21	5
M. tamariscinus	♂♀	2	24–35	6–7
M. tristrami	♂♀	2	14–17	3–4
	♂	1	25	6
	♀	1	21	6
M persicus	♂	1	19	6
	♀	1	13	3
M. meridianus	♂	7	11–14; *M* 13	3–7; *M* 5
	♀	8	4–9; *M* 7	2–3, *M* 2, 7
Rhombomys opimus	♂	7	17–27; *M* 22	5–10, *M* 7
	♀	6	14–18; *M* 15	3–6, *M* 4

Table 3. MEASUREMENTS OF THE SKIN AND OF THE GLANDULAR FIELD IN *Rhombomys opimus* (MEAN DATA)

Sample	Sex	No of animals studied	Thickness (μ)		
			Skin	Epidermis	Reticulate layer of the dermis
Midventral gland	♂	7	997	29	36
	♀	3	648	21	41
Adjacent skin	♂	5	343	21	150
	♀	2	214	20	74

The biological function of the midventral gland seems to be to demarcate territory. In the wild, *Rhombomys opimus* can often be seen to rub its abdomen against the soil. The presence of the gland in both sexes and in very young animals, as well as the fact that the gland functions throughout the year (observations were carried out on *Rhombomys opimus* maintained in the laboratory), indicates that it plays no part in the sexual function of gerbils.

Water Content in the Tissues of Desert Animals

WHEN studying *Gerbillus piramidum* and *Jaculus jaculus*, Khalil and Abdel-Messeih[1] claimed that the tissues of desert mammals contained less water than did those of non-desert ones. Several other workers (for example, the Schmidt-Nielsens[2]) found that desert animals lost less water through their skins. The data obtained by Khalil and Abdel-Messeih[1] suggest that the low water content in the tissues of desert animals (including the skin) contributes to the decreased loss in water and thus represents an important adaptation of animals to the environmental conditions of the desert.

I endeavoured to study the water content of the tissues of wild *Rhombomys opimus*, *Meriones meridianus*, *Spermophilopsis leptodactylus* and *Lepus tolai* in the Kara-Kumy desert. Samples were taken from freshly killed adults in winter (January) and in summer (June), excluding *Rhombomys opimus*. Samples of the skin (thoracic back without its hair), of the bone (femur) and of muscles (thigh muscles) were taken. Dehydration was performed in vials in a thermostat at 103° C and the water content of the tissues was calculated for the initial weight. The results of these analyses are given in Table 1.

The data obtained reveal a regularity noticed by all previous workers: the bones contained the least amount of water while the muscles contained the greatest. I was unable to confirm the data of Khalil and Abdel-Messeih[1] concerning the lower water content in the tissues of desert animals. A comparison of desert animals with non-desert ones shows that the water content of their skin and muscle is almost the same (see Table 1); however, the water content of bones of desert animals is somewhat less.

Table 1. WATER CONTENT IN THE TISSUES OF SOME MAMMALS
(The mean data in per cent)

Species	Season	No. of specimens	Percentage of water content in Skin	Bones	Muscles
Rhombomys opimus	Summer	5	65·2	28·6	79·1
Rhombomys opimus	Winter	10	56 9	33 7	76 7
Meriones meridianus	Winter	3	61·3	28 8	74·1
Spermophilopsis leptodactylus	Summer	6	65 7	29 1	80 8
Sphermophilopsis leptodactylus	Winter	7	61 6	16·9	75·6
Lepus tolai	Summer	4	65 6	—	75·8
Lepus tolai	Winter	2	66 2	—	75·9
*Gerbillus piramidum**	—	10	39 3	27·1	74·9
*Jaculus jaculus**	—	6	48 7	26 8	74·8
Cow, sheep, pig*	—	—	—	—	78–79
Dog*	—	—	55–77 3	58	68–87 3
Albino rat*	—	—	58 1–64·7	—	74·4–76 5
Rabbit*	—	—	75	—	80
Monkey*	—	—	70	61	79
Man*	—	—	58 9–72	50–55	75–78

* Data are taken from refs. 1 and 3–13.

No significant seasonal differences were revealed when winter and summer animals of the same species were compared (see Table 1). It is of interest here that a somewhat higher water content was found in both the muscles and skin of *Rhombomys opimus* and *Spermophylopsis leptodactylus* in summer.

These findings suggest that small water losses through the skin in desert animals taken for investigation cannot be explained by a difference in their water content from that of non-desert animals. Histological investigations[14] show that no morphological adaptations are present in the skin of desert animals for decreasing their water losses. On the basis of these data, it can be concluded that decreased water loss through the skin in desert animals is related to peculiarities in their endocrine and biochemical systems.

Phenomenon of Swarming in Nematodes

THE phenomenon of swarming has been observed by one of us[1] in thirteen species of plant-parasitic and free-living nematodes embracing all sub-classes of the class Nematoda. Additional reports of swarming of plant parasitic species have come from Germany[2], Kenya[3,4], and Florida[5]. Staniland's original use of the term "swarming"[6] for massing of a *Rhabditis* sp. in response to light has priority. However, in view of the unique character and general nature of the phenomenon investigated at Louisiana State University Laboratories[7–10], it is proposed to retain for it the term "swarming" and to refer to Staniland's "swarming" as Staniland's phenomenon.

Work on swarming is being continued in our laboratory, and this communication presents evidence for the induction and specificity of swarming in the genus *Tylenchorhynchus* (Tylenchida).

Dependence of swarming induction in *Tylenchorhynchus martini* Fielding 1956 on rapid and abundant host plant development[10] was confirmed by results of nutrient-sand culture experiments with rice. Swarming, after 60–75 days, occurred only where host plants were supplied with inorganic nutrient solutions containing all essential elements. Under these conditions, the use of organic supplements—asparagine, glutamine and amino-acids from acid-hydrolysed casein—had no effect on the induction of swarming, although development of rice plants was stimulated. Inasmuch as induction of the anabiotic state in nematodes occurs in unfavourable environments[11], these results reaffirm the distinctions between swarming and anabiosis. The basic outwardly visible distinction between the two phenomena is that swarmers must pull apart at a point of contact in directions perpendicular to the plane of contact; anabionts can separate by gliding motions parallel to the plane of contact.

Further evidence on specificity of swarming reactions comes from the demonstration that *T. martini* and *T. claytoni* Steiner 1933 swarm together. These results, combined with the fact that *T. martini* and an undescribed

species of *Tylenchorhynchus* from sugar-cane at Grand Isle, Louisiana, swarmed separately in mixtures[8], indicate that both species and sub-generic (group or section) specificity of the swarming reaction exist in the genus *Tylenchorhynchus*. Morphologically, *T. martini* and *T. claytoni* are close relatives, whereas the Grand Isle *Tylenchorhynchus* is distinct from these species. The combined evidence suggests that swarming specificity lies at the sub-generic group level of morphological distinctions.

Picrolonic Acid as a Hatching Agent for the Potato Cyst Nematode, *Heterodera rostochiensis* Woll.

Calam, Todd and Waring[1] reported that almost as many eggs of the potato cyst-nematode, *Heterodera rostochiensis*, were stimulated to hatch by a 3 mM aqueous solution of anhydrotetronic acid as by potato root diffusate; other tetronic acid derivatives they synthesized did not stimulate hatching. Marrian, Russell and Todd[2] synthesized various compounds based on an α-arylidene-$\Delta^{\beta\cdot\gamma}$-butenolide skeleton and reported that two of these, α-(*p*-hydroxybenzylidene)-γ-methyl-$\Delta^{\beta\cdot\gamma}$-butenolide and α-(3-methoxy-4-hydroxybenzylidene)-γ-methyl-$\Delta^{\beta\cdot\gamma}$-butenolide, "showed definite activity" at a concentration of 0·1–0·5 mM, whereas the rest were inactive or only slightly active. That anhydrotetronic acid is a good synthetic hatching agent has been confirmed[4–6], and in our tests, at 3 mM concentration, its hatch rating[3] was 90 (potato root diffusate = 100, water = 0), whereas 0·1–0·05 mM α-(*p*-hydroxybenzylidene)-γ-methyl-$\Delta^{\beta\cdot\gamma}$-butenolide was only slightly active (hatch rating 7).

Fenwick[7] and Doliwa[8] reported, respectively, that picric acid and potassium permanganate hatched eggs of *H. rostochiensis*. We tested these but found that picric acid was inactive (hatch rating 4) and potassium permanganate hatched only few eggs (hatch rating 9), whereas both hatched eggs of the beet cyst nematode, *H. schachtii*, well (hatch ratings >200 and 86, respectively)[3].

We tested the ability of more than four hundred compounds to hatch eggs of *H. rostochiensis*, using techniques already described[3,9,10], and, except for anhydrotetronic acid, found only one compound, picrolonic acid[11] (4-nitro-3-methyl-1-*p*-nitrophenylpyrazolone), which, at concentrations of 0·4–4 mM, hatches eggs as effectively as potato root diffusate (hatch rating 102). By comparison, zinc salts, which hatch eggs of several *Heterodera* spp.[9], have a hatch rating of 50 for *H. rostochiensis*. Other tetronic acid derivatives, pyrazolones and closely related compounds were inactive.

Picrolonic acid, like anhydrotetronic acid, is formed of two linked rings and has an acidic, enolic group as part of a potentially tautomeric system of two polarizable atoms separated by an extended chain.

Picrolonic acid also hatched many eggs of the soybean cyst-nematode, *H. glycines*, and some of the tobacco cyst-nematode, *H. tabacum*, but none of the cabbage cyst-nematode, *H. cruciferae*. We also confirmed that anhydrotetronic acid does not hatch *H. cruciferae*[6].

Unlike anhydrotetronic acid, picrolonic acid is a commercial product, so it is the first easily obtainable, efficient, synthetic hatching agent for *H. rostochiensis*. By contrast, more than fifty such compounds are known to hatch eggs of *H. schachtii*.

Esterase Activity in the Arachnida

DESPITE the immense amount of work which has been carried out on the physiology of the insects, there is little comparative information available for the Arachnida. The present note is a report on current studies of the comparative biochemistry of these animals.

Using polyacrylamide gel electrophoresis the esterase activity of eight species belonging to seven genera of Arachnida has been investigated. Following homogenization, supernatants containing 300γ protein/0·05 ml. were run for 24 min at a constant current of 5 m.amp per tube. The tubes were made of soda-glass and were 65 mm long with an internal diameter of 5 mm; the gels were prepared according to the method of Ornstein and Davis[1]. After electrophoresis, the gel columns were removed and incubated in the appropriate substrate media.

The reaction mixtures used were those developed by Holt and Withers[2], Laufer[3], and Gomori[4]. The distribution of protein bands was indicated by staining for 1 h in 1 per cent amido-black in acetic acid, followed by the standard de-staining procedure. The association between total esterase activity and the protein bands was demonstrated by incubation in 5-bromo indoxyl acetate for 2–4 h at 21° C; and also α-naphthyl acetate together with either fast blue *RR*, or fast garnet *GBC*, for 2 h at 21° C. Incubation in solutions of acetylthiocholine iodide and butyrylthiocholine iodide demonstrated the presence of enzymes capable of hydrolysing these substrates, that is to say, specific and non-specific cholinesterases. Work is in progress in which selective inhibitors are being used to distinguish between these enzyme types. Table 1 summarizes the results obtained for the eight species

Table 1. OCCURRENCE OF ESTERASE ACTIVITY IN EIGHT SPECIES OF ARACHNIDA

Mechanism of the Pasteur Effect

THE increase in rate of carbohydrate breakdown in peas in anoxia was earlier associated with decreases in adenosine triphosphate (ATP), oxidized diphosphopyridine nucleotide, 3-phosphoglyceric acid (3-PGA) and phosphoenolpyruvate (PEP) and with increases in adenosine diphosphate (ADP) and fructose-1,6-diphosphate (FDP)[1]. The decreases in 3-PGA and PEP were attributed to an acceleration of the metabolism of these compounds initially in anoxia; in consequence a faster rate of production of "glycolytic" ATP was inferred. We suggested that the sugar phosphorylating and glycolytic enzymes were located in an organized structure, which was effectively more permeable to ADP than to ATP. With such a structure the faster production of "glycolytic" ATP, mentioned above, should result in faster phosphorylations of both glucose and F6P than under aerobic conditions and so glycolysis would be hastened. Moreover, evidence quite different in nature from that just outlined, that is a discrimination in the use of ATP in air and in anoxia, could also be explained in terms of a glycolytic structure.

The occurrence of various important cellular processes in specialized structures, such as the nucleus, the chloroplast, the mitochondrion and the ribosome, provides a general argument for the existence of a glycolytic structure. The reason why a glycolytic organelle has not as yet been identified unequivocally could be that the structure is both smaller, and more easily disorganized by grinding, than, for example, the mitochondrion. In fact the glycolytic enzymes have hitherto been generally accepted as being "soluble" and located in the cytoplasm. Indeed in 1964 there was little evidence of the occurrence of a glycolytic organelle, but now data are accumulating which indicate that a glycolytic structure may exist.

Thus in "dried" yeast the glycolytic enzymes were not "soluble" but seemed to be located in an organized structure[2]. The enzyme carboxylase and about 25 per cent of the protein content was extracted by adding water, but the glycolytic enzymes were only extracted if the "dried" yeast was first homogenized by grinding. Moreover, the glycolytic activity of the "dried" yeast amounted to about 50 per cent of that of fresh yeast.

In other work yeast cells were ground in a mixer with glass beads and the glycolytic activity was found in fractions sedimenting at between 1,000*g* and 10,000*g*; no glycolytic activity was found in the supernatant solution[3]. But an active particulate fraction was obtained only from one strain of yeast cultured in a special manner.

In red blood cells and yeast the complete glycolytic system (including the sugar phosphorylating enzymes) was thought to exist in, or on, an organized structure, which was believed to be associated with the "membrane" of these cells[4–8]. With the procedures used the glycolytic enzymes were found both in the particulate and soluble fractions. Nevertheless, the view was favoured that the glycolytic enzymes existed *in vivo* in or on an organelle from which they were, in part, released during the preparation of the particulate fraction[7]. The "membrane" fractions were examined with an electron microscope[8]. Recently a fraction was obtained from yeast, sedimenting at 9,000*g*, which retained more than 50 per cent of the original glycolytic activity of the preparation of fragmented cells[38].

Thus our theory that the mechanism of the Pasteur effect was associated with a glycolytic structure is now supported by this evidence for red blood cells and yeast. Moreover, in yeast[9], rhododendron leaves[10,11], apples and potatoes[12] and pea segments[13,14], PEP decreased in anoxia, so that with these tissues, too, the mechanism of the Pasteur effect might be that described above. With brain in anoxia, however, when glycolysis increased from 4- to 7-fold, PEP did not decrease but rose by 2–2·5-fold, that is, proportionately less than for glycolysis[15]. Buckwheat seedlings, which do not appear to develop a Pasteur effect in anoxia[16,17], nevertheless showed the changes in phosphate compounds[18], already mentioned as characteristic of various plant tissues in anaerobiosis. This anomaly could be explained if buckwheat seedlings do not contain a glycolytic structure.

With animal tissues the Pasteur effect has been attributed to the activation of hexokinase (HK) and of phosphofructokinase (PFK) in anoxia[15,19–24] (in ref. 20 the tissue was treated with serotonin, which hastens glycolysis). Thus extracts of HK are inhibited by G6P (ref. 25) while PFK is inhibited by ATP and citrate[26], but activated by inorganic phosphorus, adenosine monophosphate, ADP, FDP and other compounds[15,21,23,27,28]. The Pasteur effect is thus attributed to the influence on HK and PFK of these various activators and inhibitors.

In the activation : inhibition theory, just mentioned, the observation that G6P decreases and FDP increases in anoxia is accepted as evidence that HK and PFK are activated in anoxia[15,20–21]. But other explanations can be given for the inverse changes in G6P and FDP in both plant and animal tissues in anoxia. Thus the high content of G6P in aerobiosis has been visualized as related to the high content of ATP in or near to the mitochondria[29–31]. With the decrease of "mitochondrial" ATP in anoxia a large decrease in G6P would be expected. The increase of FDP in anoxia has been attributed to a higher content of reduced diphosphopyridine nucleotide, this increase holding back the triosephosphate dehydrogenase and aldolase reactions[9,32]. Thus the addition of acetaldehyde to yeast, before anoxia, decreased the rise of FDP in anaerobiosis[9,32]. Moreover, in potatoes, FDP did not increase for 2 days of anoxia, while in apples this compound remained unchanged for 2 days of anoxia with one variety, but increased in a second variety; yet in both potatoes and apples the Pasteur effect developed during the first day of anoxia[12].

The time-relations of the observed changes in phosphate compounds are particularly important in relation to the mechanism of the Pasteur effect. Thus in peas the Pasteur effect was fully developed after 15 min or less of anoxia[33] and the contents of ADP, 3-PGA and PEP had decreased to new steady values in this period[1,31]; in contrast G6P did not change initially in anoxia in one experiment and may even have increased in another experiment. In rhododendron leaves[10,11] G6P increased for some 2 h in anoxia to about double the aerobic value so that in both peas and rhododendron leaves the acceleration of the HK reaction in anoxia may not be due to a decrease in G6P removing the inhibition of this enzyme by G6P, as postulated for animal tissues.

Other evidence against the validity of the activation : inhibition theory is given separately[31].

Thus for plant tissues the available evidence appears to indicate in general that the Pasteur effect cannot be explained by the activation : inhibition theory. However, because the evidence consists mainly of determinations of the total cellular contents of certain phosphate compounds, we must emphasize that both the contents and changes of the relevant substances at the enzymatic surfaces may

differ greatly from the total cellular amounts[34,35]; conclusions, based on such determinations, either for or against the validity of the activation : inhibition theory, must therefore be viewed with caution.

A puzzling feature of the Pasteur effect is that the rate of phosphorylation of sugar must be faster in anoxia than in air, although the cellular content of adenosine triphosphate is generally lower under anaerobiosis[1,9,31]. But this anomaly can be explained by the glycolytic structure theory, as an essential postulate is that the content of ATP is higher in the structure in anoxia than in air[1,31]. In contrast, according to the activation : inhibition theory, ATP would be lower in anoxia than in air, so that sugar phosphorylation would be retarded. This anomaly is generally not mentioned in descriptions of the activation : inhibition theory.

In bananas the climacteric increase in rate of respiration is associated with increases in the contents of G6P, FDP, pyruvate, α-ketoglutarate and oxaloacetate but with a decrease in the content of PEP[36,37]. Thus here, as in anoxia, the increase in respiration rate may be related to a faster rate of metabolism of PEP giving a faster rate of formation of "glytolytic" ATP.

We thank Dr. T. ap Rees, Dr. D. H. Northcote and Prof. S. L. Ranson for advice.

Antifungal Compounds in Apple Fruit infected with *Sclerotinia fructigena*

RECENTLY, Swinburne[1] reported the infection of apple fruits (var. 'Bramley's Seedling') by *Nectria galligena* and suggested that the production of an antifungal material after infection could account for an observed inhibition of the pathogen. During our investigations with fruits of a number of apple varieties we found, in agreement with Byrde[2], that the variety 'Edward VII' possesses resistance to infection by the brown rot organism, *Sclerotinia fructigena*. We have established that, when such fruits become infected with brown rot, antifungal compounds are produced which can be readily detected by biological and chemical tests.

When disks of *S. fructigena*-infected tissue from the 1963 crop were placed on potato dextrose agar, seeded with the conidia of *Alternaria brassicicola*, zones of inhibited fungal growth were found after incubation. Disks from healthy fruits gave no similar zones of inhibition (Fig. 1).

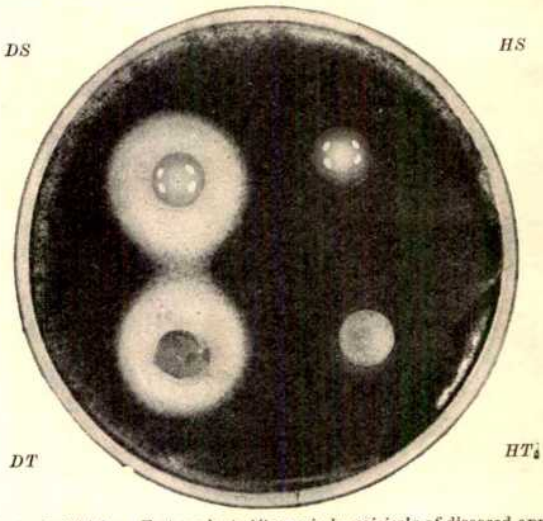

Fig. 1. Inhibiting effect against *Alternaria brassicicola* of diseased apple tissue (*DT*) and the syrup obtained from it (*DS*) compared with healthy tissue (*HT*) and its syrup (*HS*)

These observations were confirmed in experiments with apples harvested in 1964. 'Edward VII' apples (5 kg), visibly free from disease, obtained from trees which had not received fungicidal sprays, were wounded by sticking pins 2 mm long, at random, into their skins. They were then immersed momentarily in a suspension of conidia of *S. fructigena*. The inoculated fruits were kept in a humid atmosphere for eight days, by which time brown rot was well advanced and new conidial pustules were developing. After seeds and core tissue had been removed the fruits were macerated and the macerate

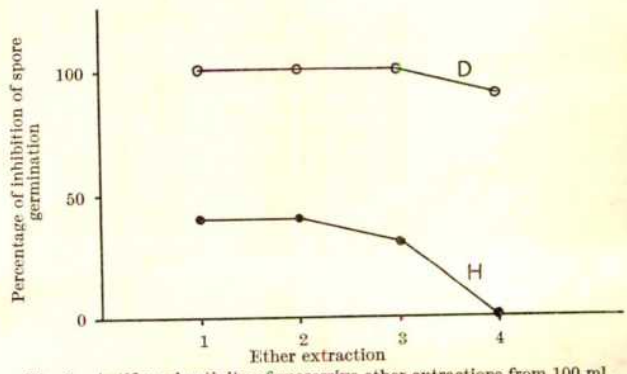

Fig. 2. Antifungal activity of successive ether extractions from 100 ml. of syrup from healthy (*H*) and diseased (*D*) apple. The residue from 0·05 ml. of each 200 ml. ether extraction was tested against *Botrytis cinerea* in 0·2 ml. of 0·2 per cent sucrose solution

was filtered. The resulting liquid (about 4 l.) was rapidly concentrated to 400 ml. by evaporation under reduced pressure at 20°–25° C. The amber-coloured residual syrup (0·1 ml.) was placed in a cavity (1 cm in diameter) in a standard potato–dextrose agar plate seeded with the conidia of *A. brassicicola* and incubated. The antifungal effect is recorded in Fig. 1. Negligible antifungal effect was observed with the corresponding syrup obtained from healthy tissue.

Equal portions of the ether extract of the syrup from diseased apples completely inhibited the germination of spores of *Botrytis cinerea* while aliquots of the corresponding ether extracts from healthy apple syrup allowed germination (Fig. 2).

On shaking the active ether extract with sodium bicarbonate solution, most of the antifungal activity passed into the aqueous phase. This was acidified to *p*H 2·5 and re-extracted with ether. Malic acid, which possesses some antifungal activity, remained in the aqueous layer. The ether extract was dried over magnesium sulphate, filtered and evaporated to dryness under vacuum at 20° C. The pale yellow, tacky solid (0·75 g of crude material from 5 kg of apples) had an ED_{50} of about 60 μg/ml. against *A. brassicicola*. It was subjected to column chromatography on acidified silica gel in benzene/ether (1 : 1) and two antifungal materials were separated.

The chromogenic reactions (Table 1) and the infra-red spectra obtained with these materials indicate that *A* is a phenolic acid and *B* is an unsaturated aliphatic acid. These substances are readily detected by paper chromatography of ether extracts of the juice from diseased apples, but they are not detectable in the corresponding extracts from healthy apples. Further chemical investigations of these acids are now being made.

GENETICS

'Kleine Liebling' a Haploid Cultivar of *Pelargonium*

IN the course of a comprehensive investigation of the chromosome constitution of *Pelargonium* species and cultivars, it has been discovered that the horticultural variety 'Kleine Liebling' is a true haploid with only nine somatic chromosomes. Kimber and Riley[1] list many records of the sporadic occurrences of haploids, both under natural conditions and in experiment, but this is the first time that the haploid condition has been so successful as to result in a vigorous and attractive cultivar which, although inevitably sterile, seems to lack any deleterious recessive genes which would naturally be exposed in a flowering plant possessing only a single set of chromosomes.

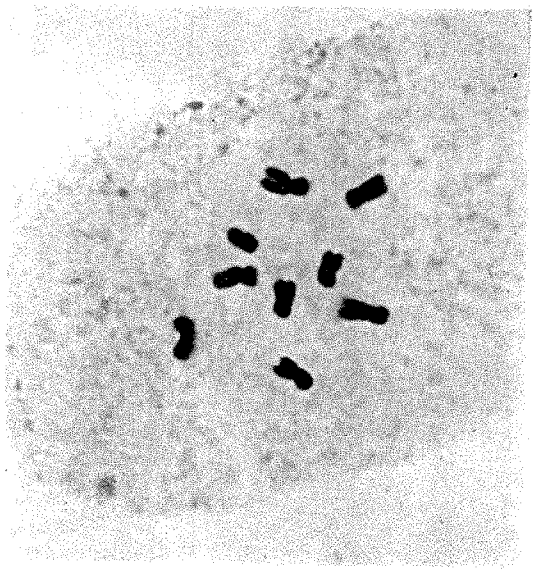

Fig. 1. Haploid root tip mitosis (× 2,000)

Pelargonium varieties are propagated almost entirely by taking stem cuttings, but the constant vegetative increase of plants carries with it the possibility of genetic variation by the conscious or unconscious perpetuation of mutants. For this reason, following the initial discovery of haploidy in one stock of 'Kleine Liebling', more chromosome determinations were made of plants from various sources and of the variegated form of this variety. The chromosome counts were also made from various parts of the plants such as roots, stem apices, and developing petals. It was found that whereas the aerial portions of the plants were invariably haploid, roots could be entirely haploid, haploid/diploid chimeras, or purely diploid, and each of these three types of root could occur on a single cutting. (Table 1 indicates the genetic constitution of both root and shoot systems for each plant examined.) This suggests that the variety is a haploid/diploid chimera, but it would be a strange chimera indeed if one of the genetically different tissues were consistently confined to the subterranean parts. If the plants were periclinal chromosome chimeras, evidence of this would be seen in the shoot apice squashes, which reveal the chromosome constitution of the *L* I, *L* II and *L* III layers; all, however, are haploid. For the same reason there is no evidence to suggest that the plants are mericlinal or sectorial chimeras in the generally accepted sense. There remains the possibility that the diploid cells are produced afresh when new plants are initiated by stem cuttings. When the cuttings were grown in water culture, it was observed that roots developed freely from the nodes. All such roots were found to be entirely haploid, but it is probable that under horticultural conditions callus tissue will form at the cut surfaces of the

* Included here are plants having both haploid and diploid roots, and also individuals with roots that are haploid/diploid chimeras.

stem, and it may well be that it is from this that the diploid roots arise.

Morphologically, 'Kleine Liebling' is characterized by the size of the leaves and flowers, which are distinctly smaller than in any other 'Zonal' *Pelargonium*; a factor that may well be attributable to the haploid condition. The origins of this cultivar have yet to be traced, but because pelargoniums are generally propagated by cuttings, it seems likely that all present-day plants have been derived from the same source, probably from a single genotype, initiated either as a bud mutation or through haploid parthenogenesis; its selection then being favoured by breeders on account of its miniature characteristics. The existence of a variegated form indicates that some gene or plastid mutation has occurred in the later development of this variety.

Further work is now in progress in an attempt to explain more fully the genetic constitution of this cultivar, but for the present it can be stated that there is little doubt that 'Kleine Liebling' owes its diminutive characteristics to the prevalence of a haploid condition which, in contrast to other monoploids, is highly successful.

SOIL SCIENCE

An Improved Method of demonstrating the Distribution of Sulphides in Peat Soils

HYDROGEN sulphide is produced under certain conditions in soils and may be an important factor in governing the distribution of higher plant species in the field[1]. Burgeff[2] describes a simple method of demonstrating the presence of sulphides in peat soils. He obtained a visual measure of the distribution with depth from the formation of silver sulphide on silver-plated brass rods. Clymo[3] used polished silver wires for a similar purpose. Work at this research station on changes in redox potentials in depth and time at four peat bog sites has required better definition of sulphide distribution than either of these methods provides. The degree of discoloration of polished silver ranges from pale gold through brown to black, and it is difficult to observe the lighter end of the colour scale on a curved surface. Furthermore, there are often considerable horizontal variations in sulphide occurrence in the field and a large number of wires would be necessary to measure such variations. By using silver plates these difficulties can be overcome.

Polished copper sheets electroplated with silver (Johnson Matthey and Co., Ltd.), 30 cm square and 1·59 mm ($\frac{1}{16}$ in.) thick, were obtained. They were pushed vertically down into the soft peat after the surface mat of vegetation and roots had been sliced with a sharp knife. Before withdrawing, by a wire hooked through the two corner holes, the peat surface level was marked on them. Any material adhering to their surfaces was then carefully washed away and they were dried with soft paper tissues.

The images which formed on the plates were photocopied on to 'Ilfoprint' Contact Paper by exposure for 4·5 sec in a Dalcopier photocopy machine, and positives were prepared from these. This provided a permanent record of the distribution of sulphides at each site every month. The photocopies have the further advantage of eliminating the mirror effect of the plates and are consequently easier to examine. Two examples are shown in Fig. 1*A* and *B*.

Fig. 1*A* was from a *Sphagnum cuspidatum* pool on Striber's Moss, a relatively undisturbed estuarine raised bog in North Lancashire, and Fig. 1*B* was from the adjacent Deer Dike Moss. Deer Dike Moss has been extensively drained and burned, with the result that the surface is now dry and devoid of *Sphagnum*. Both plates were left in the peat for 1 h 30 min on July 9, 1965.

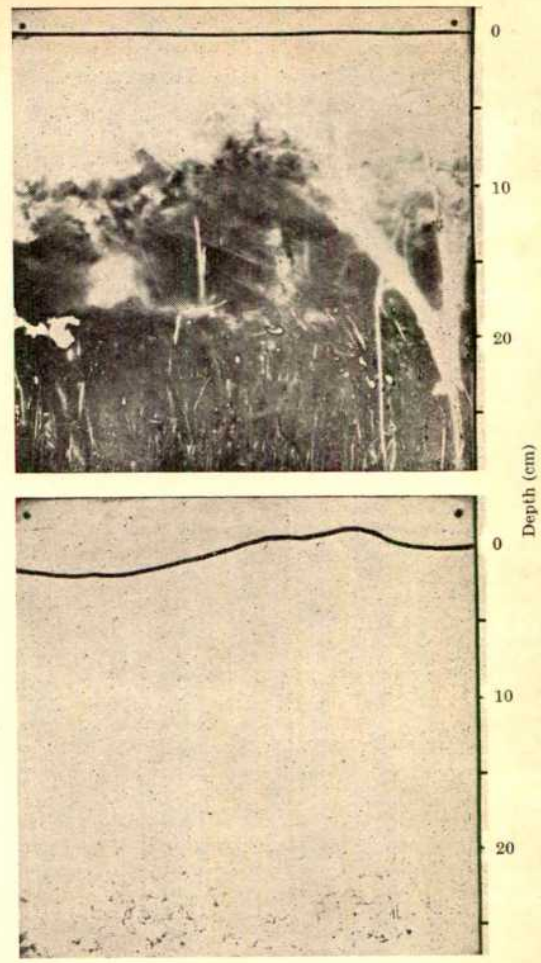

Fig. 1. Distribution of sulphide in the surface layers of an undrained (*A*) and a drained (*B*) raised bog peat profile. The profile surface is marked at the top of each figure

A striking feature of Fig. 1*A* is the silhouette of an *Eriophorum angustifolium* plant against which the plate had been deliberately placed. It is also apparent that large quantities of sulphides were present in this profile. *E. angustifolium*, however, would seem to be a plant species which is not inhibited by the sulphide. Armstrong found that oxygen diffused rapidly from the roots of this species, and the silhouette may indicate that oxygen was diffusing from the entire plant surface, and had locally prevented the formation of silver sulphide.

The irregular sulphide-free areas with intensely marked outlines on Fig. 1*A* are similar to those described by Burgeff[2] and probably arise from gas bubbles in the peat.

Fig. 1*B* illustrates the greater depth and very sparse local distribution of sulphide at Deer Dike Moss.

I thank Mr. A. J. P. Gore for his helpful advice and discussion.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURERS IN BIOCHEMISTRY (one in general biochemistry and one in biochemistry in relation to veterinary studies)—The Secretary of the University Court, The University, Glasgow (August 4).

ASSISTANT LECTURER or LECTURER IN THE DEPARTMENT OF VETERINARY ANATOMY—The Registrar, The University, Liverpool, quoting Ref. CV/145/N (August 5).

ASSISTANT LIBRARIAN (with a good honours degree and preferably with a higher degree, professional diplomas and library experience)—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 5).

RESEARCH ASSISTANT IN AERONAUTICS to take part in the work directed towards the development of apparatus for a new high-speed aerodynamics laboratory, or alternatively, in the development of experiments on zero-gravity environmental studies—The Secretary of the University Court, The University, Glasgow (August 5).

HEAD (preferably interested in the inter-relationship between the mineral nutrition of plants and the feeding value of the forage produced) OF THE SOILS DEPARTMENT—The Secretary, Grassland Research Institute, Hurley, Maidenhead, Berkshire (August 8).

LECTURER or ASSISTANT LECTURER (preferably with research experience in fields other than soils or dairying, for example, food or taxonomy) IN THE SECTION OF FOOD AND AGRICULTURAL BACTERIOLOGY IN THE DEPARTMENT OF AGRICULTURE—The Registrar, The University, Leeds, 2 (August 8).

RESEARCH ASSISTANTS (with a degree or equivalent in biochemistry or chemistry) IN THE DEPARTMENT OF BIOCHEMISTRY for work on research projects in the following fields: muscle biochemistry, development and use of automation in amino-acid analysis, biochemical aspects of photosynthesis, and the metabolism of insect flight muscle—The Assistant Registrar (Science and Engineering), P.O. Box 363, University of Birmingham, Birmingham, 15 (August 8).

PHYSICAL CHEMIST or BIOCHEMIST (with a good honours degree in chemistry or biochemistry) IN THE N.E.R.C. MARINE BIOLOGY UNIT to investigate proteins associated with the settlement of marine organisms—The Registrar, University College of North Wales, Bangor, North Wales (August 10).

RESEARCH ASSISTANT (Non-medical) (with a B.Sc. with biochemistry as a main subject) IN THE UNIVERSITY DEPARTMENT OF PATHOLOGY, Western Infirmary, Glasgow, for research work on human autoimmunity and will consist largely of fractionation of tissues and serum proteins—Secretary of the University Court, The University, Glasgow (August 10).

ASSISTANT (with an honours degree in agricultural chemistry or biochemistry, and preferably postgraduate experience in agricultural chemistry) IN THE CHEMISTRY DEPARTMENT at Auchincruive for advisory investigational teaching duties—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow, C.2 (August 12).

LECTURER (preferably with experience in microbiological chemistry, microbial genetics or an applied field of microbiology) IN BACTERIOLOGY at Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee (August 13).

SYSTEMS ANALYST (preferably with a degree or professional qualification and a knowledge of accountancy procedures) to develop new data processing systems for the University's administration and library—The Deputy Secretary, The University, Southampton (August 15).

COMPUTER PROGRAMMER (Technical Officer) (graduate with an ordinary degree in mathematics, computing and/or statistics an advantage) IN THE DEPARTMENT OF PUBLIC HEALTH AND SOCIAL MEDICINE for work which will be concerned with building up a suitable library of programmes in all aspects of medical research—The Secretary, University of St. Andrews, Queen's College, Dundee (August 19).

EXPERIMENTAL OFFICER and a TECHNICIAN (preferably with experience in mass spectrometry and/or electronics) to assist in the running of a unit for isotope geology being set up at the Reactor Centre—The Director, Scottish Research Reactor Centre, East Kilbride, Glasgow (August 20).

LECTURER or SENIOR LECTURER IN BOTANY at Fourah Bay College, The University College of Sierra Leone—The Inter-University Council, 33 Bedford Place, London, W C 1 (August 24).

ASSISTANT ADVISER (qualified man aged at least 45 with substantial practical experience of improving animal health and the livestock industries overseas, particularly in tropical conditions) based at the Ministry of Overseas Development London headquarters, but duties will involve travel to overseas countries to which H.M. Government furnishes assistance in the field of animal health—The Civil Service Commission, 23 Savile Row, London, W.1, quoting Ref. 6469/U (August 25).

COMPUTING ASSISTANT (with a good honours degree in mathematics or in a pure or applied science and preferably an interest in statistics and/or operational research)—The Secretary, The University, Leeds, 2 (August 26).

LECTURER/SENIOR LECTURER (with an interest and experience in one or more of the following fields: non-numerical computations, the use of computers in operations research, or the use of computers for control) IN THE BASSER COMPUTING DEPARTMENT, School of Physics, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 26).

LECTURER IN PHYSICAL or INORGANIC CHEMISTRY—The Assistant Registrar (Science and Engineering), P.O. Box 363, The University of Birmingham, Birmingham 15 (August 27).

PROFESSOR IN THE DEPARTMENT OF ZOOLOGY at the University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 27).

LECTURER (able to teach plant physiology to first-, second- and third-year students and supervise research for higher degrees) IN THE DEPARTMENT OF BOTANY; and a LECTURER IN CONTROL SYSTEMS IN THE DEPARTMENT OF ELECTRICAL ENGINEERING at University College, Nairobi (University of East Africa)—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 28).

LECTURER or ASSISTANT LECTURER (preferably with an interest in solid state physics or holography) IN PHYSICS at Queen's College—The Secretary, University of St. Andrews, Queen's College, Dundee (August 29).

SENIOR LECTURERS, LECTURERS, or ASSISTANT LECTURERS IN CHEMISTRY; a SENIOR LECTURER, LECTURER or ASSISTANT LECTURER (preferably with a special interest in applied mathematics) IN MATHEMATICS; and a SENIOR LECTURER or LECTURER (preferably qualified to advise on research design and on the use of computers) IN STATISTICS at the University of Zambia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 30).

DIRECTOR OF THE INSTITUTE OF EDUCATION, University of Zambia—The Inter-University Council, 33 Bedford Place, London, W.C.1 (August 31).

LECTURER/ASSISTANT LECTURER (graduate with teaching and/or research experience in micrometeorology, environmental physics or cognate fields) IN ENVIRONMENTAL PHYSICS—The Registrar, University of Nottingham, Nottingham (August 31).

LECTURER (member of the Royal College of Veterinary Surgeons) IN THE DEPARTMENT OF ANIMAL HUSBANDRY AND VETERINARY PREVENTIVE MEDICINE—The Secretary of the University Court, The University, Glasgow (August 31).

LECTURER or ASSISTANT LECTURER IN MICROBIOLOGY IN THE DEPARTMENT OF BOTANY—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (August 31).

READER (medically qualified) IN IMMUNOLOGY at the Institute of Cancer Research—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 31).

READER or SENIOR LECTURER (with a registrable medical qualification, a higher degree or other higher qualification) IN MEDICINE at the University of Adelaide, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, August 31).

ASSISTANT LECTURER (with special qualifications and research interests in petrology, geochemistry or economic geology) IN THE DEPARTMENT OF GEOLOGY—The Registrar, The University, Nottingham (September 1).

CHAIR OF PHARMACOLOGY at Chelsea College of Science and Technology—The Academic Registrar, University of London, Senate House, London, W.C.1 (September 1).

ASSOCIATE PROFESSOR OF PSYCHOLOGY (in the field of abnormal and clinical psychology) at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 5).

CHAIR OF PSYCHOLOGY and HEAD OF THE DEPARTMENT OF PHILOSOPHY AND PSYCHOLOGY at the University of Hong Kong—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, September 15)

SENIOR LECTURER IN SOCIOLOGY—The Registrar, University College of South Wales and Monmouthshire, Cathays Park, Cardiff (September 15).

CHAIR OF MATHEMATICS (Data Analysis) at the University of Canterbury, Christchurch, New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, September 16).

LECTURER or SENIOR LECTURER IN THE DEPARTMENT OF STATISTICS, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 23).

LECTURER/SENIOR LECTURER IN VETERINARY MICROBIOLOGY IN THE DEPARTMENT OF VETERINARY PARACLINICAL SCIENCES, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 1).

RESEARCH ASSISTANT (graduate (or equivalent) in physics, engineering, or textile technology) IN THE DEPARTMENT OF TEXTILE TECHNOLOGY, to work on the development of woven, knitted and other fabrics—The Registrar, University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1, quoting Ref. W.F. (October 1).

LECTURER/SENIOR LECTURER (with considerable chemical experience) IN PHARMACOLOGY at the University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 14).

RESEARCH ASSISTANT (graduate (or equivalent) in physics, engineering, or textile technology) IN THE DEPARTMENT OF TEXTILE TECHNOLOGY, to work on unconventional weaving machinery—The Registrar, University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1 (October 15).

BIOCHEMIST (B.Sc. or A.R.I.C.) in the Group Department of Biochemistry—The Hospital Secretary, Chase Farm Hospital, The Ridgeway, Enfield, Middlesex, quoting Ref. 191/66.

GEOLOGISTS (preferably with experience of structural investigation and drilling supervision or the computations of quantities) for coal prospecting in the United Kingdom—The Staff Manager, National Coal Board, Opencast Executive, Coal House, Lyon Road, Harrow, Middlesex, quoting Ref. S.V. 235(B).

MATHEMATICIANS to work on a wide range of problems arising from research into the utilization and distribution of electricity (topics include: arc physics, electro chemical reaction kinetics, solid state devices, magnetism, electrical distribution systems, heat transfer, and the application of mathematics to life science)—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Chester, quoting Ref. N/29.

ORGANIC CHEMIST (experienced in the synthesis and use of compounds labelled with radioactive isotopes) for the Chemical Research Team which is studying certain chemical aspects connected with tobacco smoking and human health—The Personnel Officer, Tobacco Research Council Laboratories, Harlow Hill, Harrogate, Yorkshire.

POST- or PRE-DOCTORAL RESEARCH ASSISTANT to assist in an investigation of Ziegler-Natta catalysed polymerization using radio-active isotopes—The Secretary, Queen Elizabeth College (University of London), Campden Hill Road, London, W.8.

RESEARCH ASSISTANT (preferably with experience in one of the following fields: gas dynamics, electrical discharges, combustion) IN ELECTRODYNAMIC GENERATION OF POWER—Dr. J. Lawton, Chemical Engineering and Chemical Technology Department, Imperial College, London, S.W.1.

RESEARCH ASSISTANT (science graduate with a knowledge of microscopy) for laboratory work related to coronary thrombosis—The Secretary, Institute of Cardiology (University of London), 35 Wimpole Street, London, W.1.

RESEARCH ASSISTANT to take part in a study of the oxidation of organic compounds by high oxidation state transition metal halides and oxyhalides; and a RESEARCH STUDENT to participate in studies of free radical reactions of organic compounds—The Vice-Principal, Kingston College of Technology, Penrhyn Road, Kingston upon Thames, Surrey.

RESEARCH STUDENTS (with a good honours degree in physics) IN PHYSICS—The Registrar, The University, Sheffield.

RESEARCH STUDENTS (with a good honours degree or equivalent in physics or mathematics) IN THEORETICAL NUCLEAR PHYSICS—Prof. L. R. B. Elton, Department of Physics, Battersea College of Technology, London, S.W.11.

SENIOR LECTURER IN BIOCHEMISTRY; a SENIOR LECTURER IN PLANT PHYSIOLOGY; and a LECTURER IN MICROBIOLOGY—The Principal, Barking Regional College of Technology, [illegible]ge Road, Dagenham, Essex.

SENIOR LECTURER (with [illegible]n microbiological physiology/biochemistry) IN BIOCHEMIS[illegible]ipal, Bromley Technical College, Bromley, Kent.

SENIOR TECHN[illegible]chemical pathology) to work in the new Ren[illegible] with the Medical Unit—The House Go[illegible]n, London, W.2.

SHOESTRING RESEARCH

THE tale of recent events at the British Food Manufacturing Industries Research Association on page 561 is not intended as entertainment. Those who hear of it will sympathize with all the parties concerned, the Council of the Association, the members of the Association, the laboratory staff and, most especially, the Director until October 11, Dr. C. L. Cutting. Most probably there have been mistakes on all sides. It remains unclear precisely how the future of the Research Association will work out, especially because a re-organization is having to be worked out at a time when British industrialists are scarcely likely to want to dig deeper into their pockets for a larger subscription. No doubt the Council will consider that it does not at this stage need to be embarrassed by unsolicited advice from outside. Though the Research Association may be comparatively small, its affairs raise issues of some importance.

The first thing to be said concerns the job of directing research in a laboratory of any size—in industry, government or a university. In one way or another, administration is an inescapable part of the job. The staff has to be kept happy, by being given a sense of purpose and in much more humdrum ways as well. Those who pay for the research have to be told what they are getting for their money—and persuaded to pay for more. Those who could make use of the work have to be shown how to do so. Then the broad strategy of the research programme has to be embodied in a host of small and apparently tedious decisions about the best kind of spectrometer to buy for the laboratory, or whether to send the laboratory assistants out for extra training. A director can, of course, be helped enormously by good advice, but in the last resort decisions must be his. To the extent that the Council hoped that they could operate a different system, it is to blame for what has happened. That, it is to be hoped, will be a comparatively easy lesson to learn.

It is much harder to see how the more enduring anomalies in the Association's organization are to be dealt with. Perpetual near-penury is a bad sign, and one that marks some other co-operative industrial research associations in Britain. Ironically, however, the food manufacturing industry is one of the largest, with a turnover of something like £5,000 million a year. Why is its co-operative research laboratory able to raise only a derisory fraction of this sum by subscription from food manufacturers? And how can the Association hold its head high when some individual member companies spend ten times as much in a year on their own food manufacturing research?

As at present organized, the Association is plainly trying to do too much with its meagre resources. The result is that it can neither command the respect of the big food manufacturers nor satisfy the diverse demands of the small members. And in trying to satisfy the needs of those who would pickle gherkins without loss of colour, and those concerned with the seeds in raspberry jam, the Association does not seem to have been able to pay as much attention as it should have done to the common and urgent problems of food manufacturers—the problems of hygiene and adulteration about which society is rightly becoming increasingly concerned. The best of all outcomes from the trouble at Leatherhead would be a determination by the food industry to see that it is not respectable to keep its research association so starved of funds that it is incapable of doing any job properly. The minimum subscription, at present fixed at a little more than £25, is, of course, derisory. It ought promptly to be multiplied by a factor between four and ten. If the result should be that some companies decide to cancel their membership altogether, nobody should worry. The doctrine of the co-operative research association is that the pooling of resources should make possible a more effective effort in research, but some of the food manufacturers appear to think that their association is just a way of getting research on the cheap.

The implications of what has happened at Leatherhead for research associations elsewhere cannot easily be spelled out. The signs are that the Food Manufacturing Industries Research Association is exceptional. Certainly the research associations concerned with iron and steel, or welding, have all the flair and freedom that good laboratories should possess. Scale is not crucial, for some quite small research associations are among the most effective. Yet the faults which are concentrated in the Food Manufacturing Industries Research Association are also those which tend to give the research associations as a whole a somewhat colourless and unattractive air. Members do often regard the associations as a complete substitute for research on their behalf, with the result that research programmes are needlessly fragmented. Councils do often exert too close a control on programmes of research, or keep too tight a hold on the moneybags. And staff tends to be down-trodden. Nobody should be surprised that the research associations—with some exceptions—find the recruitment of good people a perpetual headache. This is especially unfortunate in Britain at this time, for the associations are so well connected with industry that they should be able to do more than most organizations to help with the modernization of British industry.

TEACHING CHEMISTRY

THE Royal Institute of Chemistry has a splendid record in education. For several years it has worked hard on schemes to introduce modern ideas to teachers of chemistry in the schools. A year ago it broke new ground with a series of conferences for teachers, and if these were less successful than more permanent arrangements for teacher training would have been, the Institute is not the organization to blame for that. A measure of the Institute's educational ambitions is the fact that it is trying to raise £100,000 to finance a number of educational projects. One of the first things to be attempted is a study of the relationship between undergraduate and postgraduate courses at British universities, and this will provide an important part of the background to a conference on university education in chemistry due to be held in Manchester next January. That promises to be a valuable exercise.

With all this evidence of virtue, it is surprising that the Institute has so far done very little to remove the anomalous impediments to the transfer of bright young men and women from British schools to departments of chemistry at the universities. These are peculiarly British problems, and consequences of the bizarre practice of specialization in the schools. Like many other organizations, the Institute has been worried about them for some time. The most alarming symptom of what is wrong is the stagnation of so many of those who leave school at eighteen with a qualification in chemistry. In circumstances in which senior pupils must usually specialize in three subjects, chemistry has suffered more than physics, biology and mathematics from the attractiveness of newer studies such as economics. Yet British universities remain curiously inflexible in what they ask of intending entrants to chemistry departments. At most British universities, those with their eyes on a career in chemistry must present themselves with examination qualifications in mathematics, physics and chemistry. One immediate absurdity is that only a tiny handful of British graduates in chemistry have ever studied biology except at an elementary level. A more insidious evil is that young people inevitably suppose the rigidity of the regulations for entering a chemistry department to be a sign that chemistry itself is a kind of straitjacket. By requiring that young people wishing to take up chemistry at university should so resolve at sixteen, the same rigidity probably ensures that many potential chemists finish up in other disciplines.

These tendencies are probably a sufficient explanation of why chemistry has been lagging behind other scientific studies in the interchange between British schools and universities. All the Institute's work on the in-service training of teachers, and its willingness to spend liberally from its limited resources, can only be a palliative. It is like trying to cure measles by painting out the spots. Sooner or later there will have to be a direct attack on the problem of the demands made by the universities on would-be entrants to chemistry departments. As things are, the chemists are outdone in conservatism only by the mathematicians. The universities will have to recognize that they cannot rely indefinitely on the schools to supply them with stereotyped young chemists. If the alternative should be a fourth year at university, the chemists should not shrink from saying so.

SOBER SOCIAL SCIENCE

THOSE who may with justice have been afraid that the creation of the Social Science Research Council would be a device for subsidizing and perpetuating second-rate academic work at the universities should now be comforted. The first list of grants awarded by the Council is as respectable as anybody could ask. Altogether the Council has allotted £150,000 to eighteen projects. The recipients are as distinguished as they are well known. There is some straightforward social anthropology in Western Nepal and a study of kinship and support in pregnancy. Economics does well, and the study of the making of decisions in public enterprises which Prof. R. L. Meek is undertaking should be useful as well as interesting. The Council has done well to find a project on the development of cognitive skills in children, for too little work of that kind is being carried out in Britain, and there is a useful list of projects in what may properly be called industrial anthropology—the consequences of redundancy among the workers in a factory in South Wales, for example. It is particularly welcome that the Council should be supporting a study of the experiment at the Fairfields Shipyard in Glasgow whose ownership has been transferred to the British Government and certain trade unions.

Why, then, have academics been afraid of what the Social Science Research Council would attempt? And can they now relax, putting their trust in Dr. Michael Young and his committee? The difficulty, of course, is to know what is meant by social science. The several recent authorities on the subject, and particularly the Heyworth Committee, have been deplorably vague, with the result that too much attention has been drawn to pronouncements tending to suggest that any ill-considered set of concepts can be turned into a piece of science by a sufficient array of numerical information and a few applications of the chi-squared test. More seriously, except in fields such as economics, it is still uncommonly difficult to extract general conclusions from the kinds of studies to which social scientists appear prone. Having asked the wives of miners in Yorkshire how they spend their housekeeping money, there is often nothing to do but to put the same questions to miners' wives in Nottingham. Avoiding repetitious projects of this kind will be a constant headache. The temptation to lower standards will be great. The Social Science Research Council has begun well, but it will be helped by being watched closely.

NEWS AND VIEWS

Vienna Safeguards

THE International Atomic Energy Agency seems to have taken a still firmer grip on the problem of safeguarding the uses to which nuclear fuels are put. In the past few months it has been working out a procedure for extending the existing safeguards regulations, finally approved a year ago, to apply to reprocessing plants as well as nuclear reactors. The working group responsible for the original system was re-convened in February this year, and extensions to the safeguards system were approved by the Board of the Agency in June. This step, described in the annual report of the Board of Governors for the year ending on June 30, 1966, will go a long way to meet the criticisms of those who have argued that the control of re-processing plants is more important than the control of nuclear reactors in preventing the misuse of fissionable material.

An impressive number of nuclear installations now comes under the umbrella. By the beginning of 1967, it is expected that seventy-five installations with an electrical capacity of 4,500 MW will be concerned. The Agency is also planning to develop automatic monitoring devices which may make it possible for inspectors to follow some of the physical operations at reactors without being on the spot. Of the fifty-four reactors subject to safeguards at the end of June 1966, only seven were power reactors capable of producing more than 20 MW of electricity. The cost to the Agency of these activities is still relatively modest, and is expected to amount to just under half a million dollars in 1967.

The complete budget is a reminder that the Agency is still a relatively small organization. The total staff, from the doorman to the Director-General, will number 729 in the coming year. The estimate for 1967 of $11·9 million is actually somewhat less than for the preceding year. More than three-quarters of this sum will be spent on administration, but there is also room for some scientific work. The Vienna laboratory will take $200,000, and the International Centre for Theoretical Physics at Trieste a little more. The Monaco Laboratory will use $45,000, and the programme of technical assistance and training will cost nearly $2 million. As a whole, the record of good works is so respectable that it is all too easy to forget the troubles which attended the Agency's formation a decade ago, and which may yet break about its head.

Farmers' Weather

THE hope of a more trusting relationship between farmers and meteorologists was clearly to be inferred from a conference sponsored by Unesco and held last week at the University of Reading. It was the first international symposium on "Methods in Agroclimatology" and was attended by more than 120 people from thirty-six nations—meteorologists, agronomists, horticulturalists, foresters and even physicists. The purpose of the meeting was to survey the present contribution of meteorologists to agronomy, and to see what further benefits can be obtained.

It is not, of course, surprising that links between meteorology and agriculture are difficult to create. At Reading it was clear that efforts are now needed in almost diametrically opposed directions. First, there is a need to examine meteorological processes on the micro-scale so as to study the effect of the environment on the growth of plants, the productivity of animals and the epidemiology of pests and diseases. But, at the same time, there is also an urgent need for practical surveys on a macro-scale. Work of the second kind is indeed one of the essential needs of agricultural planners, particularly in developing countries where the rapid development of agriculture has to be guided by pure reason and not by the accumulation of unformulated tradition which determines agricultural practice in well-developed countries. Yet it was also plain, from the papers read at Reading, that experienced countries such as Japan and Great Britain have much to gain from the full exploitation of climatic potential. There was, for example, a detailed survey showing how more fruit could be grown in western counties of England.

A proof of the success of macro-surveys was the set of papers describing the surveys carried out by agencies of the United Nations, principally Unesco, FAO and WMO, in semi-arid areas. The general feeling at the symposium was that these surveys were a good beginning, and greatly to the credit of those who had carried them out. At the same time, it was now necessary to fill in some of the details of the relationship between climate and agricultural potential, particularly in the Levant and south of the Sahara.

The conference was also concerned with the modifications of the relationship between climate and agriculture which may be brought about artificially by irrigation and the provision of shelter, for example. There was also some speculation about different trends of climate. The conference was reminded that comparatively small changes of climate have in the past contributed to the downfall of nations, particularly around the Mediterranean, and that future plans for the development of land may be vitiated by similar alterations of the limits on agricultural practice. At the symposium there were also some suggestions as to how agriculturalists might codify their perpetual game with the weather along the lines spelled out by the games-theorists. Throughout, the mood of the conference was opposed to the view that it will be easy to make full agricultural use of climatic potential.

Fuel Enough

THE O.E.C.D. has taken a cautious but cheerful line in its most recent report on the balance between the supply of energy and the demand for it. The calculations and extrapolations of the group of officials responsible for the report suggest that between now and 1980 "resources are largely adequate to cover any foreseeable demand". More cheerfully still, it is thought probable that this comfortable balance can be achieved without moving too far from the present cost of energy.

Within the O.E.C.D. area as a whole, which includes North America and Japan as well as Europe, the increasing competitiveness of nuclear energy and of natural gas are given as the principal sources of price stability in the decade or so ahead. Nuclear energy, in particular, is said to be on the way to being "fully competitive in the near future". The authors of the report consider that nuclear energy will tend to set a

ceiling to the price at which fossil fuels can be sold for power production in the seventies.

The projections in the report are based on the assumption that the industrial production of the O.E.C.D. area will continue to grow without significant interruption. The demand for energy will march in step. It is expected that total consumption in the O.E.C.D. area will increase from the equivalent of 2,200 million tons of oil (in 1964) to 4,300 million tons of oil by 1980. One novel feature of these forward estimates, however, is a levelling tendency, for the rate of increase of demand is expected to be smallest in those countries in which energy is at present used most intensively—principally the United States. By 1980 it is reckoned that the United States will account for 60 per cent of the demand for energy within O.E.C.D., Europe for 30 per cent and Japan for the remaining 10 per cent. The total demand for energy in Eastern Europe and the Chinese Republic is expected to amount to 2,800 million tons of oil equivalent in 1980, or roughly 65 per cent of the then demand within O.E.C.D. The corresponding ratio in 1960 was roughly 51 per cent.

The forward projections for nuclear energy are more optimistic than previous forecasts by the O.E.C.D. By the mid-eighties nuclear power may account for 35 per cent of all electricity production in North America, and as much as 40 per cent in Europe. Then natural gas from the North Sea suggests at least the possibility that what has already happened in North America may also happen in Europe. The report says that this is an exciting prospect, and then goes on to suggest how individual nations should frame their policies so as to take advantage of the flexibility provided by a diversity of sources of supply. In passing, even the operators of coalfields can glean some comfort, for there is a solemn passage about the great size of the reserves of fossil fuel. This is a report to please everybody.

Who Needs Support?

LIKE foundations elsewhere, the Alfred P. Sloan Foundation of New York is hard at work trying to devise ways of keeping ahead of government support for science and for education. In his report for 1965, the President of the Foundation, Mr. Everett Case, says that the increased support from the U.S. Federal Government for scientific research at the universities and for students at college "has involved it in fields once largely the province of private initiative". Pointing to the scale on which the U.S. Government is at present supporting scientific research and education, Mr. Case says that "it is futile for private philanthropy to compete against the government". The report says that the federal government has not yet taken to supporting undergraduates and scientists in the early stages of their careers in precisely the way in which the foundation is anxious to do so, but clearly Mr. Case thinks it is only a matter of time before the government catches up. He is evidently hoping that a systematic appraisal of the outcome of the Foundation's grants in recent years may make possible an objective review of foundation policy, and then throw up suggestions of new fields for philanthropy to conquer.

Grants worth $13 million were awarded in 1965, mostly in scientific research and education. The Sloan-Kettering Institute is still high on the list of beneficiaries. The Foundation also seems to derive continued pleasure from open-ended grant-giving. Thus it has given $5 million to Stanford University as an expendable fund for research in the physical sciences, and has continued the programme by which university scientists, usually at the post-doctoral stage, are awarded fellowships detached from particular programmes of research. This is in line with the Foundation's view that too rigid a link between university research and the award of grants and contracts from outside may interfere with academic freedom. The Foundation also allocated $500,000 during 1965 to an imaginative scheme for supporting Negro male students at ten predominantly Negro colleges in the United States. The foundation stands out by its willingness to support schemes for the popularization of science, and is supporting the Scientists' Institute for Public Information and also the work of the Council for the Advancement of Science Writing in running training courses in science journalism.

Smithsonian 1965

THE annual report of the Smithsonian Institution for the year ended June 30, 1965, shows an appropriation of $15·54 million, of which $5·84 million was for the United States National Museum, $1·25 million for the Astrophysical Observatory, $319,601 for the National Air Museum, $179,640 for the Canal Zone Biological Area, $114,648 for the Bureau of American Ethnology, and $113,330 for the International Exchange Service. In his covering statement the Secretary, Dr. S. Dillon Ripley, refers to the establishment of an Office of Special Projects on the bicentenary of the birth of James Smithson, the founder, and says that one of the objects of that office is to examine the nature of knowledge and creative discovery as understood to-day.

The Museum of Natural History had a busy year. Members of its staff discovered the presence on Dominica of the snail *Planolina glabrata* (Say), the intermediate host of schistosomiasis. The close relation between agave and yucca has been proved beyond doubt in a study of yucca moths. An ancient connexion has been found between the fauna of Repa (in the mid-Pacific) and those of Australia, New Zealand and South Africa, and preliminary research in the Valley of Oaxaca, Southern Mexico, has verified the presence in many caves and rock shelters of abundant perishable remains of human occupation and shown that the corn cobs, cactus fruits and other associated artefacts came from the period 6500–2500 B.C.

The Radiation Biology Laboratory has developed instruments to measure the spectral quality of sunlight, in 100 mμ bands, from sunrise to sunset throughout the year. Further information was acquired on the chemical structure of polyphosphate compounds in marine organisms and algae. The Prairie network of automatic cameras for the simultaneous photography of very bright meteors went into full operation and the sensitivity and accuracy of the Harvard-Smithsonian Meteor Radar Network has been improved. New measurements have been made of radioactive and stable isotopes in meteorites and in dust samples from the Greenland Icecap and elsewhere.

Drop More Names

HAVE the bad old days when it was only possible to get on by knowing the right people gone for good?

Alas, no. An instrument recently introduced requires just this kind of intellectual nepotism, yet without the necessary personal acquaintance. Given a subject, a handful of top names and a library stocked with complete runs of some 20,000 top science journals, the *A–Z* of the subject is potentially at hand. The fundamental idea behind the *Science Citation Index*, of which the first quarterly volumes for 1966 have now become available, can be summed up in the phrase: "What has happened since ?" In other words, what has a man published, and who, in what publication, in any scientific field, has cited any of his works since they were published ?

Each quarterly issue consists of three massive volumes, two for the citations and one for recent sources. The former provide under name (or journal if anonymous), patent number or corporate body, every citation during the quarter in more than 1,500 journals, together with the names of those responsible for the citation, where and when. The companion *Source Index* provides chapter and verse of all new sources published in the quarter, and gives names of authors, titles of articles, journal, volume and page number, etc. It is estimated that when the 1966 *Index* is complete, 3·4 million cited references will have been listed from 300,000 new source items. At an annual subscription of $1,250 (educational rate) or $1,950 (all others), the *Index* is likely to be accessible only to those research institutions which already have, or are likely to obtain, a computer. Thus now that the searching technique by way of citation is being widely accepted, the compilers of the *Index*—the Institute for Scientific Information, Philadelphia—should be investigating the possibilities of putting it on tape.

Better Writing

THE report of the conference held earlier this year by what is known as the "Presentation of Technical Information Group" has now been published. The group seems to have recruited a company of speakers willing to say that scientific writing is bad and ought to be improved. It was apparently less successful in winning agreement about what should be done. Several speakers said that scientific appointments should go only to those able to demonstrate some skill in writing, but they were naturally somewhat reticent in suggesting how regulation should be imposed on the universities and the laboratories. The benefits of formal courses in language and writing for science undergraduates and postgraduates were extolled by some. Like most bodies that would change some aspect of society, the group seemed to think that the schools should be doing more, but there seems to have been some uncertainty about the need to encourage writing for self-expression in the schools. One opinion sent in after the conference was that "less emphasis could well be placed on self-expression and more on writing to supply information that somebody else needed to know".

Copies of the report may be had at 6*s*. from Mr. A. K. Parker, Godolphin Cottage, Gog Magog Hills, Babraham, Cambridge.

Abstracts on Tape

WHAT can be done with abstracts of the literature embodied on reels of magnetic tape ? The Chemical Society and the University of Nottingham are planning a research programme to explore the usefulness in a British context of the abstract service based on a computer system which is now being supplied by the American Chemical Society. The intention is that magnetic tapes from the United States will be processed by a unit under Dr. Anthony Kent, previously a lecturer in zoology at Nottingham, who will be the director of what will be known as the Chemical Society Research Unit in Information Dissemination and Retrieval. The title is evidently intended to suggest that both the Chemical Society and the university have in mind a continuing programme of research and development, and a statement by the Society says that its aim is to provide in Britain a comprehensive and mechanized information service comparable in every way with that now becoming available in the United States.

To begin with, at least, the Society is financing the project out of its own resources. By doing so it will put British chemists much where British medical research workers now find themselves as a result of the experiments being conducted from Newcastle as part of the MEDLARS programme. A related but necessarily more complicated programme of development is now being undertaken by the Institution of Electrical Engineers, which is responsible for publishing *Physics Abstracts*. That programme, which is being carried out in close collaboration with the American Institute of Physics, is financed by a grant from the Office of Scientific and Technical Information.

Virology Journal

THE Society for General Microbiology is to produce, and the Cambridge University Press is to publish in January 1967, a new journal called the *Journal of General Virology*. It will be edited by Dr. C. Kaplan of the Lister Institute of Preventive Medicine and Professor P. Wildy of the University of Birmingham. The Society for General Microbiology, which also publishes the *Journal of General Microbiology*, intends to divert virological papers to the new journal which will, however, not seek to publish clinical or epidemiological articles.

Podzol Jubilee

DR. H. KLINGE of the Max Planck Institut für Limnologie writes on the twenty-fifth anniversary of the publication by P. W. Richards[1] of "Lowland Tropical Podsols and their Vegetation":

"Before Richards's paper, podzols had been recognized and described from areas with cool-humid climates in temperate regions and on tropical mountains. From tropical lowlands of Borneo, white or bleached sand soils with a coal black or dark brown layer at some depth had been reported and the peculiar physiognomy and floristic difference of the vegetation from the surrounding normal equatorial rain forest mentioned[2,3]. Richards, however, was the first to realize that these soils are widespread in tropical lowlands in the Guianas, the Amazon and in Malaya, where they are always associated with a physiognomically peculiar vegetation and with blackwater rivers.

"Tropical podzols, being unsuited to profitable permanent agriculture, are considered important to forestry[4] and have therefore attracted much interest. This is borne out by the appearance of about four hundred publications concerning tropical podzols[5],

most of which deal with the soils themselves. Some hundred deal with tropical podzol vegetation and the remainder are concerned with tropical blackwater–podzol relationships. Of the seventy papers which appeared before 1941, a dozen were quoted by Richards.

"A considerable amount of information is now available on the distribution pattern of tropical groundwater and well-drained podzols; but no estimate is yet possible of the area covered by these soils, which mostly occur as scattered small patches. They are known to exist along the east and west coasts of Africa, at a few places in the Congo, and on the islands of Mafia, Pemba and Madagascar. Their distribution is wide in tropical South-East Asia and in tropical and subtropical Australia. They cover extensive parts in Florida and in the Guianas, and are also found in patches in the Caribbean region and in the Amazon basin. Despite the wide distribution in the tropical rain forest area, the actual proportion of the land surface occupied in the areas is rather small.

"Not all tropical bleached or white sands[6–8] are true podzols characterized by clay destruction[9], but immature soils on white sand deposits, occasionally overlying buried soils[10], or top layers of soils characterized by clay migration only.

"In his study of the tropical podzol vegetation, Richards referred to caatinga forests of the Amazon basin, Wallaba forests and Muri bush of the Guianas, heath forests (kerangas), padangs or mattangs of the Malayan region and noted that the forest types in the different regions were more closely related to each other than to the native mixed tropical rain forest. Podzols are now known to exist under grassy vegetation (Amazonian wet campos), campina forests of the Amazon, restinga forests of eastern Brazil, and coastal savannas of Africa. A feature of these more open plant communities is that they may include plant species of the genera *Drosera*, *Sphagnum* and *Cladonia* which also occur on temperate podzols.

"Richards saw the primary cause of podzolization, within the region of perhumid climate of the equatorial lowlands, in the low content of the parent material of bases and clay-forming materials. As a consequence, base-deficient soils develop on which, owing to this deficiency, raw humus accumulates. Raw humus accumulation is well known as a prerequisite for subsequent podzolization, so that the occurrence of this process in the tropical lowlands could be explained in this way. Richards's view has since been confirmed. The parent material on which tropical podzols predominantly develop are loose and consolidated sands. That these are mainly of marine origin would explain the frequent association of these soils with coastal plains, or fluviatic sands of river basins or outwash materials, or finally also acid volcanic rocks. Tropical podzols, however, have also been found to develop from latosolic parent soils[11]".

Parliament in Britain

IN reply to questions in the House of Commons on July 28 regarding progress in establishing a University of the Air, the Parliamentary Under-Secretary of State for Education and Science, Miss Jennie Lee, said that the preliminary survey, including costs and television channels, had been completed. The figures were extremely encouraging and she considered that more could be done for more people at less cost in higher education once the project was under way than in any other part of the education field. The proposals would most certainly not be shelved: an open university had become an urgent necessity in Britain's circumstances to-day.

IN the House of Commons on July 26, Mr. H. Jenkins was given leave to introduce, under the Ten Minute Rule, a Bill "to restrain nuisance by aircraft noise; to restore freedom to pursue actions against aircraft owners and operators for nuisance by noise and vibration; to empower the President of the Board of Trade more effectively to limit and to restrain aircraft noise; and to empower the Parliamentary Commissioner to enquire into and report on all such questions". The Bill would seek to reduce the permitted level of noise from the present 110 perceived noise decibels by day and 102 decibels by night, to 100 noise decibels immediately and then to 90 noise decibels over 5 years. The Bill would also provide a defence against any actions against aircraft owners and operators if it could be proved that a noise level of no more than 100 decibels was being produced at the time.

IN a written answer in the House of Commons on July 18, the Minister of Technology, Mr. A. Wedgwood Benn, stated that, during the three years to March 1966, his department had spent £12,000, £6,000 and £77,000 towards the development of fuel cells. The National Research Development Corporation had spent £18,000 up to May 1966, and British Rail and the Gas and Electricity Councils were also giving attention to fuel cells as part of their research programmes. The Minister intended to seek better arrangements for co-ordinating this work. There was much to be done before manufacture of an economic working system became possible.

IN the House of Commons on July 28 the Tees Valley and Cleveland Water Bill was given a third reading after an amendment, moved by Mr. M. Kimball, had been rejected by 112 to 82 votes. The Bill, which authorizes the Tees Valley and Cleveland Water Board to construct a reservoir in the Cow Green Area, is strongly opposed by the Nature Conservancy and the National Parks Commission. The scientific argument, which was put forcibly by Mr. Kimball, Mr. A. Blenkinsop, Sir John Eden and Sir David Renton, was not met by the supporters of the Bill, nor has it been by spokesmen for Imperial Chemical Industries, Ltd. The Minister of Land and Natural Resources, Mr. F. Willey, who had already given reluctant approval to the proposal, admitted frankly that an area of unique scientific interest would be prejudiced or damaged, but chose to accept the advice of the Water Resources Board rather than that of the Nature Conservancy and to spend another £12 million over 60 years.

In reply to questions in the House of Lords on July 25, the Minister of Defence for the Royal Air Force, Lord Shackleton, said that the functions and powers envisaged for a National Council for Oceanic Resources were already vested in the Natural Environment Research Council, which was responsible for supporting and co-ordinating research in this field. The Council had set up two specialist sub-committees, for oceanography and fisheries and for geology and geophysics. Exploration for oil and gas was carried out under licences granted by the Minister of Power, and information obtained by the licensees in the course of their operations must be made available to the Natural Environment Research Council's Institute of Geological Sciences. Lord Shackleton said that the Council's Oceanography and Fisheries Committee included the Fisheries Departments, and also representatives of the Hydrographer, the Admiralty Research Laboratories, the British Ship Research Association, and the Ministry of Overseas Development. It was very strong indeed on the marine biological side, and real progress had been made. There was also much international co-operation in this field. The International Council for the Exploration of the Sea was mainly concerned with the North-east Atlantic and there was also the Inter-governmental Oceanographic Commission of Unesco as well as other special agencies, and Lord Shackleton was very encouraged by the progress being made.

In reply to questions in the House of Lords on July 28 about the National Reference Library of Science and Invention, Lord Hilton of Upton said that a Working Party of officials was set up early this year to determine the requirements of the Library. When these had been settled, which it was hoped would be before the end of 1966, detailed planning of the new building would begin. The recent decision to move the Patent Office out of London had affected the scheme, necessitating a revision of building plans, and had led to renewed discussions with the Greater London Council over the lease of the South Bank site. The Minister of Education and Science was well aware of the importance of obtaining a suitable site as soon as possible.

University News:

Cambridge

Following the appointment of Prof. F. P. Bowden to the chair of surface physics, the name of the laboratory he is directing, which was formerly Physics and Chemistry of Solids, has been changed to Surface Physics, Sub-Department of the Cavendish Laboratory, Free School Lane, Cambridge.

Edinburgh

Dr. P. M. B. Walker has been appointed to the chair of natural history in the Department of Zoology. The following have been appointed to personal chairs: Dr. M. Pickford (physiology); Dr. J. A. Strong (medicine); Dr. J. R. Greening (medical physics).

Liverpool

Mr. G. H. Lawson has been appointed to the newly established chair of business studies. Mr. J. A. Proudlove has been appointed to the newly established chair of transport studies. Dr. J. Stringer has been appointed to the chair of physical metallurgy in succession to Prof. D. Hull, who was recently transferred to the Henry Bell Wortley chair of metallurgy.

London

Prof. R. W. H. Sargent has been appointed to the Courtaulds chair of chemical engineering, tenable at the Imperial College of Science and Technology. Dr. W. L. L. Rees has been appointed to the chair of psychiatry, tenable at St. Bartholomew's Hospital Medical College.

Newcastle upon Tyne

Mr. J. R. O'Callaghan has been appointed to the chair of agricultural engineering. The following have been appointed to personal professorships: Mr. J. Shaw (zoology); Mr. D. N. Walder (surgical science).

Swansea

Prof. P. M. Davidson has been appointed head of the Department of Physics for the session 1966–67. Dr. J. Dutton has been appointed to a chair of physics. Mr. H. W. Gosling has been appointed to a second chair of electrical engineering.

Appointments

The new director of the Tata Institute of Fundamental Research, Bombay, is to be Prof. M. G. K. Menon. He is primarily known for his contributions to cosmic ray research, and indeed worked in the cosmic ray group under Prof. C. F. Powell at Bristol University between 1949 and 1955. Prof. Menon joined the Tata Institute in 1955 and became senior professor and deputy director (physics) in 1964.

The following have been appointed to the Medical Research Council: Prof. D. A. K. Black, University Department of Medicine, The Royal Infirmary, Manchester; Prof. W. T. J. Morgan, Department of Biochemistry, Lister Institute of Preventive Medicine. These members have been appointed in succession to Prof. G. M. Bull and Prof A. Neuberger. Prof. W. S. Feldberg has been appointed head of a new Laboratory of Neuropharmacology at the National Institute for Medical Research.

Mr. R. F. Turnbull, a senior principal research scientist in the C.S.I.R.O. Division of Forest Products, has been appointed Australian chief scientific liaison officer and scientific adviser to the Australian High Commissioner in London, in succession to Mr. W. Hartley.

Announcements

Under the auspices of the International Union of Pure and Applied Chemistry, the University of Michigan is now making publicly available the *Bulletin of Thermodynamics and Thermochemistry*—an unusual kind of abstracting publication. The *Bulletin* breaks new ground by printing lists, frequently accompanied by short summaries, of articles in the process of being published by the journals. It also includes a comprehensive bibliography of papers in thermodynamics and thermochemistry published in the past year (1965). The volume of the *Bulletin* now available is the ninth to have been produced, but the first to have been published. Because of increasing size and rising costs, the *Bulletin* has had to seek support from the National Science Foundation, which has provided capital to launch the enterprise.

The Association of Scientific Workers in Britain has taken a stand against the British Government's incomes policy. In a statement issued at the end of July, the Association says that it has consistently opposed the Government's policy and that it will "oppose with even greater vigour" the proposal that there should now be a "freeze" on wages in Britain. The statement says that the Association considers "the relative technological backwardness of some sections of industry, the need to expand rapidly in

education, health and housing and the need to increase exports" cannot be solved by a restraint on wages and salaries.

THE Ministry of Defence (Royal Navy) says that the time signal service, which since January 1, 1966, has been provided by Criggion VLF station (*GBZ*) on 19·6 kc/s while the Rugby station was modernized, will revert to Rugby (*GBR*) on 16 kc/s, as from 0001Z on September 1, 1966.

IT is planned to have early in 1967 a special issue of *Radio Science* devoted to the subject of the propagation of long radio waves. Experimental and theoretical workers in this field are invited to submit manuscripts for consideration, and further information can be obtained from the Editor, Radio Science, Environmental Science Services Administration, Boulder, Colorado 80302.

PROF. F. SONDHEIMER, who since 1964 has been holding a Royal Society research professorship at the University of Cambridge in the University Chemical Laboratory, will, from October 1, 1967, be holding his appointment in the Department of Chemistry at University College, London. The University has conferred the title of professor of chemistry on Prof. Sondheimer in respect of his appointment.

THE Canadian Society for Cell Biology was formed at a meeting held in the Queen's University, Kingston, Ontario, during May 19–20, with an executive consisting of: *President*, Dr. H. F. Stich (McMaster University); *President-Elect*, Dr. L. Simmovitch (University of Toronto); *Secretary*, Dr. S. T. Bayley (National Research Council, Ottawa); *Treasurer*, Dr. G. Setterfield (Carleton University); *Directors*, Dr. S. J. Webb (University of Saskatchewan); Dr. J. G. Lafontaine (Laval University); Dr. M. Barr (University of Western Ontario); Dr. P. Ford (University of British Columbia).

THE third international Congress of Nephrology will be held in Washington, D.C., during September 25–30. Further information can be obtained from the Secretariat of the Congress, 9650 Wisconsin Avenue, Washington, D.C.

A CONFERENCE on "Hazards in Foundries", organized by the British Occupational Hygiene Society, will be held in the University of Birmingham during September 13–14. Further information can be obtained from Mr. D. C. Murphy, Medical Department, Esso Petroleum Co., Ltd., Esso Refinery, Fawley, Southampton.

THE sixth international symposium on "Gas Chromatography and Associated Techniques", organized by the Gas Chromatography Discussion Group of the Institute of Petroleum, will be held in Rome during September 20–23. Further information can be obtained from the Institute of Petroleum, 61 New Cavendish Street, London, W.1.

A SYMPOSIUM on "Gastrointestinal Radiation Injury" will be held in Richland, Washington, during September 25–28. Further information can be obtained from Dr. M. F. Sullivan, Biology Department, Battelle-Northwest, P.O. Box 999, Richland, Washington.

THE third international meeting on "Organic Geochemistry" will be held at the Imperial College of Science and Technology during September 26–28. Further information can be obtained from Dr. G. D. Hobson, Department of Geology, Imperial College of Science and Technology, London, S.W.7.

A GENERAL discussion of the Faraday Society on "Colloid Stability in Aqueous and Non-Aqueous Media" will be held in the University of Nottingham during September 26–28. Further information can be obtained from the Assistant Secretary of the Faraday Society, 6 Gray's Inn Square, London, W.C.1.

A SYMPOSIUM on "Bionic Models of the Animal Sonar System", sponsored jointly by NATO and the Office of Scientific Research of the United States Navy, will be held in Frascati during September 26–October 3. Further information can be obtained from Dr. R. G. Busnel, Laboratoire de Physiologie Acoustique, Domaine de Vilvert, Jouy-en-Josas, S. et O.

A CONFERENCE on "Energy Beams and their Uses", arranged by the Electronics Group of the Institute of Physics and the Physical Society, will be held in the University of York during September 28–30. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A RESIDENTIAL conference on "Integrated Process Control Applications in Industry", arranged by the Institution of Electrical Engineers, will be held at the Manchester Institute of Science and Technology during September 26–29. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, London, W.C.2.

ERRATUM. Dr. B. G. Gowenlock has been appointed to succeed Prof. F. Bell to the chair of chemistry in the Heriot-Watt University, and not Dr. B. Glover as stated on p. 225 of the July 16 issue of *Nature*.

CORRESPONDENCE

Unpublished Literature

SIR,—Your trenchant criticism of the proposed Physics Information Exchange Scheme (PIE) (*Nature*, July 23, 1966) rather suggests that you do not find much wrong with the present system of publishing the results of scientific research. I do not share your Candide-like attitude.

In the first place publication is often far too slow.

Secondly, the practice of selection by referee is open to considerable objection. Many people have had the experience of having a paper rejected, or worse still rewritten in an unacceptable form, by one journal, and subsequently promptly accepted by another. Moreover, though it does not happen often and has certainly never happened to me, there do appear to be instances in which a referee has abused his privilege and started work based on an idea gained from a paper sent by a journal for his opinion before the article was published.

Thirdly, in order to keep abreast of progress even in one limited field it may be necessary to see regularly several dozen journals.

The Immunopathology Exchange Group (IEG), of which I am a member and which seems to be very non-exclusive, is to me of enormous value and I am most delighted both to read and to contribute to its scientific memos. Of course IEG has its critics and no doubt there is room for improvement in regard to distribution and perhaps in other ways, but it does represent a new approach to the quick dissemination of scientific information which goes far to overcome the disadvantages of conventional publication, some of which I have listed above. I know little about high energy physics, and nothing about PIE beyond the information in your editorial, but the scheme sounds as if it might help physicists in the way that IEG helps immunologists. One would hope that a journal of such high standing as *Nature* would have adopted a less timid and more constructive attitude to such an important experiment.

Yours faithfully,

MICHAEL WOODRUFF

Professor of Surgical Science,
University of Edinburgh.

ORGANIZATION OF A RESEARCH ASSOCIATION

RESIGNATIONS AT THE BRITISH FOOD MANUFACTURING INDUSTRIES RESEARCH ASSOCIATION

A PERIOD of dispute and misunderstanding about the management of the British Food Manufacturing Industries Research Association culminated on July 11 with the resignation of the Director of Research, Dr. C. L. Cutting, and the Secretary, Mr. D. H. Martin. For some months a firm of management consultants, Urwick Orr and Partners, has also been surveying the work of the organization, which is sited near a number of other co-operative industrial research associations at Leatherhead, Surrey.

Dr. Cutting has a distinguished record of work in the handling and processing of food. A physical chemist by training, he joined the Department of Scientific and Industrial Research in 1937 and worked at the Torry Research Station, Aberdeen. During this period he worked on the development of a mechanical kiln for the smoking of fish, and that device has since been widely used as the Torry Kiln. Dr. Cutting moved to the Humber in 1952, where he was responsible for building up a new laboratory concerned with fish technology, and where he also carried out a series of measurements of the temperatures at which fish were to be found at various stages of their journey from the North Sea to the fishmongers' slabs. Dr. Cutting became director of the British Food Manufacturing Industries Research Association on February 1, 1962.

A part of the cause of the disputes of the past four years seems to be the arrangements made for the management of the Research Association from the time of Dr. Cutting's arrival. It appears to have been decided that the new director should have as much time as possible to direct the scientific research of the Association, and that certain administrative responsibilities should be shouldered by the secretary of the Association.

These arrangements, designed though they may have been to assist the smooth running of the laboratory, seem to have been a source of friction. Sometimes it appears to have been difficult to decide whether the secretary of the association was responsible to the director of research or to the Council of the Association, possibly through the Finance and General Purposes Committee and its various sub-committees. Proposals for the purchase of new equipment had to be costed in such great detail that the director got the impression that he was not master in his own house. Though the director was responsible to the Finance and General Purposes Committee for recommending individual salary increases for his staff, he was not always present when decisions were made on matters like these.

The general level of salaries for research workers at the Association appears to have been another bone of contention. In 1962, the cost of salaries, superannuation and national insurance for the then staff of eighty-seven, thirty-seven of whom were scientifically qualified, amounted to £85,000. Since then there have been improvements in both salary and pension rights, and the most recent development is that the Association has adopted the salary scales of the Scientific Civil Service as a basis for the payment of its own research staff, with certain reservations concerning matters such as the timing of salary increases. Because of the proposal to increase salaries, the Association expects that income will not cover expenditure during 1966. Even so, the discontent of the staff seems not to have been fully allayed, at least in part because they were not fully informed about the reservations attached to the decision that the salary scale of the Scientific Civil Service should be adopted at Leatherhead. For one thing, the issue of salaries at the Food Manufacturing Industries Research Association has been taken to the Ministry of Labour by the Association of Scientific Workers, which claims the membership of a majority of the staff at Leatherhead. Another sign of continuing discontent is that the loss of staff from the laboratory during 1965 amounted to thirty-six (compared with fifteen in the previous year), or rather more than a third of the total staff.

These events have taken place in what seems to have been an atmosphere of impoverishment going back at least to the foundation of the Association in 1946 by the amalgamation of the British Association of Research for the Cocoa, Chocolate, Sugar Confectionery and Jam Trades and the British Food Manufacturers Research Association. Over the years the membership of the Association has steadily grown, and now amounts to close on 700, yet income by way of subscriptions lies between £90,000 and £100,000. The subscriptions of individual member companies range from £25 to £1,500. The Government, through the Ministry of Technology, contributed £47,000 in 1965—calculated as half the value of the subscription revenue from British companies. One of Dr. Cutting's contributions to the work at Leatherhead has been to increase the contributions from contract research for public authorities in Britain and elsewhere. The Association's work on cotton-seed oil and meat under contract with the U.S. Department of Agriculture was worth close on £12,000 in 1965. Work of this character for public authorities in Britain often ranked for grant from the Ministry of Technology.

The other outstanding feature of the work of the Research Association is the diversity of its scientific research. Inevitably the balance of effort reflects the interests of the subscribers, which means that confectionery and products made from meat and fish account for the greater part of the Association's effort. But it also attends to the problems of jam makers, picklers, bakers wishing to use materials such as ready-made icing, and food manufacturers concerned with edible oils. In its meat research, the Association has made some valuable contributions to the understanding and the control of bacterial contamination. Its programme of research is now being coordinated closely with that of the Meat Research Institute at Bristol, financed by a statutory levy on the meat industry.

In all the circumstances, it is more than probable that the Association will find itself having to make a drastic re-alignment of its policies in the months ahead, and in the light of the eventual report of the management consultants. A more secure source of a larger revenue is obviously a first objective, and there is no doubt that other research associations will take the greatest interest in the attempts that will no doubt be made to persuade member companies to pay larger subscriptions. It will also be surprising if the Association does not find itself looking for a more tightly-knit research programme. Getting staff—and keeping them—will not have been made easier by the events of the past few years. Going out of business cannot be altogether out of the question.

BIOLOGY OF SYNCHRONOUS FLASHING OF FIREFLIES

By DR JOHN BUCK and ELISABETH BUCK
Laboratory of Physical Biology, National Institutes of Health, Bethesda, Maryland

REPORTS of synchronous rhythmic flashing by fireflies in South-East Asia have been appearing for more than two hundred years. Smith's[1] description of displays along the Chao Phraya (Meinam) River south of Bangkok will serve to introduce the phenomenon: "Imagine a tree thirty-five to forty feet high thickly covered with small ovate leaves, apparently with a firefly on every leaf and all the fireflies flashing in perfect unison at the rate of about three times in two seconds, the tree being in complete darkness between the flashes . . . Imagine a tenth of a mile of river front with an unbroken line of *Sonneratia* trees with fireflies on every leaf flashing in unison, the insects on the trees at the ends of the line acting in perfect unison with those between. Then, if one's imagination is sufficiently vivid, he may form some conception of this amazing spectacle." The flashing, Smith continues, is confined to male fireflies and ". . . occurs hour after hour, night after night, for weeks or even months . . .".

This behaviour is strikingly different from that of most fireflies in other parts of the world: in fact, such large-scale, long-lasting, concerted rhythmic activity is seemingly unique in the animal kingdom. For this reason the phenomenon has been a perennial source of interest tinged with scepticism[2]. Yet the many accounts have not led to a consensus about certain important observational details of the synchrony, or to satisfying explanations of either the physiological mechanism of the mass flashing or of its biological significance.

On the basis of a recent visit to Thailand[3] and Borneo[4] we have reported elsewhere[5] some photographic and photometric measurements on a Thai species of firefly indicating that the synchrony of flashing varies less than 16 msec in a cycle of 560 msec, and have described observations on the build-up of synchrony under laboratory conditions which shed some light on the physiology of this firefly's "sense of rhythm". In this article we shall consider some more speculative aspects of Oriental concerted flashing related to its distribution and possible function. Two general premises are involved. First, the whole behaviour pattern, since it represents the product of countless millenia of evolutionary selection, must have a definite and important function in the life of the participating firefly species. Secondly, Oriental mass synchronism is a complex of behaviours (congregation *per se*, congregation in trees, choice of trees near water, flashing, synchrony) which may or may not be functionally related and which probably have quite different relative importances.

Riverbank Firefly Congregations

Morrison[6,7] and Smith claimed that the male Thai fireflies fly out from the adjoining jungle each evening ". . . for the purpose of engaging in this nightly display"[1]. This statement implies that the trees are populated anew each evening, an idea which we believe to be incorrect. Not only were riverbank trees near Bangkok full of fireflies in early evening, but we also found many of the insects present in mid-morning in a tree which we had studied the previous evening. Fireflies have also been seen by day in trees harbouring synchronizing swarms in New Britain[8] and in non-synchronous trees in Jamaica[9]. In Sarawak we found the tree inhabitants still flashing at midnight and at 6 p.m., as did Haneda[8] in New Britain. Resident fireflies thus account for at least part of the successive evening congregations. Fireflies were indeed seen flying to communal trees in both Thailand and Sarawak, but at the same time some were also seen flying away. The possible significance of these flights will be discussed later.

Practically nothing is known about the longevity of fireflies in Nature, but even at carefully controlled humidities and temperatures captive adults of most species die in a few days. This suggests that congregations that maintain themselves for weeks or months must be replenished constantly. Because a West African firefly species has been found to breed throughout the year[10], and the adults of several species in Jamaica[11] and in New Britain[12] are active in every month, tropical firefly trees could presumably be maintained for long periods, perhaps indefinitely, by recruits from a population in a more or less steady state of reproduction[13].

So far as it is known, all adult fireflies come from pupae in the soil—the pupae come, in turn, from larvae that live on or in the soil, or in water. Haneda found mating pairs and larvae on the ground in the Botanical Garden at Rabaul near silk-cotton trees in which fireflies were flashing synchronously. However, the mangroves bordering the swamp rivers of Thailand and Borneo stand in mud that is scoured by tidal currents so swift that it seems impossible that larvae, even if aquatic, could survive on the riverbank. Thus the swarms of fireflies in the trees must migrate from the interior swamp.

Good firefly trees were not common along the Chao Phraya River, but even in Sarawak, where the terrain is much closer to virgin swamp and firefly trees were more abundant, there were many mangroves of the same kind as those in which firefly swarms occurred, and similarly situated, which were completely free of the insects. The observed distribution of the firefly population therefore requires more than random flight from hinterland to the edge of a river. When watching male Thai fireflies in a darkroom we discovered that there is a period, before the flying specimens alight and synchronism begins to build up, when they are definitely attracted to each others' light[5]. This positive phototaxis suggests that male fireflies arriving at the fringe of riverbank trees would be attracted by flashing congregations there, or, if no previous swarm existed, might themselves form a nucleus by mutual photic attraction. Such assemblies might be expected to build up competitively, leading eventually to one or a few large swarms that had outdrawn nearby smaller centres because of higher mean light emission. Many potential display areas may therefore exist for each that develops to a spectacular level. The corollary that a good display tree would take some time to establish agrees with other indications that the assemblages are not renewed nightly.

The fact that flashing behaviour changes (from rapid twinkling to a steady tempo of two per second) after the male fireflies alight[5] is not a peculiarity of the particular Thai species or of the perching habit. Flash patterns in resting fireflies are usually quite different from those in flight[14]. What is unusual in tree fireflies is the maintenance of steady spontaneous flashing while perched—almost all roving fireflies flash irregularly, if at all, while at rest.

In sum, riparian firefly trees may be viewed as quasi-permanent assemblies, formed by way of photic attraction and maintained by recruitment.

Congregation Trees

An association of fireflies in South-East Asia with "certain", "favourite" or "particular" trees, especially mangroves, is widely recognized. In New Guinea the so-called "firefly mangrove" is *Sonneratia caseolaris* (which includes the former *S. obovata*, *S. acida* and *S. lanceolata*)[15]. The trees are well known to the natives and are said to be used in nocturnal navigation[16]. *Sonneratia* is also the "exclusive" firefly mangrove in Thailand, according to Morrison and to Smith (but see later). In Malaysia, although *Sonneratia* is common, the genus *Avicennia* must be considered an important firefly perch as its Malay name, "api-api", is also a name for firefly[17].

In Sarawak we found riverbank fireflies congregated in *Scyphiphora hydrophyllacea* and *Lumnitzera* sp. (near Kampong Senari), *Sonneratia alba* (Paya Paloh and Bako Park), *Avicennia marina* (Bako Park) and *Sonneratia caseolaris* (Paya Paloh)[18]. It was not uncommon to find *Sonneratia* and *Avicennia* trees growing side by side, each harbouring fireflies. Flashing was also seen in trees identified by our guides as mango and sago. Around Bangkok most assemblies were in *Sonneratia*, but one of our best displays in terms of population density and completeness of synchrony was in a small thorn bush (*Acanthus ilicifolius*). Synchrony was also seen in *Ziziphus mauritiana* and in another, unidentified, tree. The only instance of perch selection in either Thailand or Borneo was a negative one involving the ubiquitous nypa (nipa) palm (*Nypa fruticans*) on which it was rare to find even a single firefly.

Numerous other trees have been mentioned as firefly perches (see particularly Millard[19]), but even our own very limited experience is sufficient to show that there can be no causal relation between synchronous flashing, or even congregation, and particular kinds of trees. Nevertheless, the evidence confirms an essential involvement of trees in firefly behaviour. There has been no previous attempt to analyse this association aside from Morrison's vague suggestion that there may be ". . . something in the sap . . . which attracts the animals". This particular possibility seems very unlikely in view of the variety of acceptable trees and the very long duration of the displays, but in any event our samples of branches from firefly trees did not give any indication that the insects were being attracted by flowers or fruit. Fireflies in a Jamaican swarm have been seen possibly drinking from palm fruit scars, but the same species also congregates on acacia[9]. Furthermore, it is generally believed that most fireflies do not feed during adult life. On the whole, therefore, the evidence is very strong that trees are not an objective in themselves but are involved incidentally to some other firefly activity.

Aggregation and Mating

Since it is firmly established that male and female of most, if not all, roving-type fireflies are brought together for mating by individual-to-individual photic signalling, it is natural to enquire whether the flashing congregations in trees have any sexual significance. Both Morrison and Smith specifically denied this possibility but their stand was based on the misapprehension that female fireflies are always wingless and thus would be unable to reach the trees. The fact is that females of the riverbank species we studied in Thailand and Borneo are present in the trees, and in large numbers. The same situation was found in firefly trees in New Britain by Haneda. The females do not participate in synchronous flashing with the males, but this perhaps re-inforces the suspicion that they are in the trees for another purpose.

In the Jamaican trees large numbers of coupling pairs were found and the suggestion was made that the aggregating behaviour serves to promote mating[9]. Haneda similarly felt that the synchronous flashing of the New Britain male fireflies calls the females. In Thailand we unfortunately concentrated so hard on observing and recording the various kinds of flashes in the trees[5] that it was not until we had returned to the United States that we realized the significance of possible non-luminous activity (most fireflies cease flashing while mating). We did find a coupling pair on the gunwhale of our canoe after we had beaten the foliage with our insect nets in making a mass collection, and we observed that such beatings always flushed out many more animals than we would have expected from the density of flashing. Thus mating presumably does occur in the firefly trees of Thailand as in Jamaica and New Britain.

One further tenuous indication of mating habits comes from eye size. It is fairly well established that in firefly genera in which a roving male seeks a sessile female the eyes of the male are much larger than those of the female; but if the female takes a mobile part in the courtship the eyes are more nearly equal in size. In all the species of riverbank fireflies we have examined the eyes of the males and females are about equal. This finding is compatible with the idea that females as well as males are attracted to the congregations. Nets placed around a small firefly tree might give evidence of the postulated two-way (but not necessarily luminous) traffic and might make it possible to ascertain whether incoming females are primarily virgin and departing females mated[20].

Possible Rationale of Mass Mating

If fireflies do convene at the water's edge for mating, the utility of trees as fixed and dry sites for assembly is obvious, particularly since the insects do not mate on the wing. The assembly trees would presumably be selected by chance, and mangroves, being common, would be used often. However, it is not obvious why the riverbank should be chosen for assembly in the first place or why the fireflies in question should have evolved indiscriminate centralized mating instead of the system of individual courtships, which is not only the more usual plan among fireflies but would appear to be more efficient in terms of dispersal of the species.

In most species of roving firefly, males in an already widely distributed population search on the wing for stationary females. Recognition and homing depend on the pair being able to see each other nearly continuously in order to distinguish the signal code of their own species from those of other species patrolling the same terrain. Our experience with American, Caribbean and upland Malayan[21] forms indicates, as might be expected, that roving fireflies are found primarily on open ground, such as meadows, forest glades, road clearings, savannah and jungle trails.

There could scarcely be imagined a terrain less favourable for line-of-sight recognition than the flat, tangled, mangrove-nypa swamps of South-East Asia in their virgin state. A firefly tree on a watercourse, however, might provide a sufficiently bright and large beacon, perhaps enhanced by reflexions, to attract fireflies that wander out into the clear over the water, and might provide enough opportunities for mating to compensate for the (assumed) long flights required of the mated females for egg dispersal. We propose therefore that, in tropical swampland, mass mating has evolved instead of pair courtship because sustained photic communication between individuals is impossible.

Significance of Mass Synchrony

As reported elsewhere[5], not all the firefly trees which we saw in Thailand showed concerted flashing, and the trees we studied in Sarawak, where synchrony has been seen by professional biologists[22], showed only transitorily and incompletely co-ordinated flashing. We suspect that we failed to see well-developed synchrony in Sarawak because at the time of our visit the riverbank trees were harbouring approximately equal numbers of three species of fire-

flies (all of the genus *Pteroptyx*[23]), with consequent clashing of rhythms and breakdown of entrainment. Even in Thailand, where two other species of *Pteroptyx* were together in the trees, the synchrony of the dominant males only produced its wondrous effect because the numbers of the second species were very small. In Thailand we also felt that synchrony was more complete in more densely populated trees, in line with our "laboratory" finding that the visual feedback that brings two individuals into step operates only over relatively short distances[5]. It seems likely, therefore, that a species of firefly capable of flashing synchronously may produce displays ranging from apparently perfect unison to completely random sparkling depending on such factors as population density and purity.

There is little indication that synchronization of flashing is essential for either development or maintenance of arboreal congregations of fireflies. However, if the insect eye reacts like the human eye there are two reasons why synchronous emission would be more effective than disordered flashing as a beacon for assembly. An obvious effect would be to change a relatively continuous luminescence to an alternation of light and dark. (This principle is, of course, widely used in advertising signs in order to enhance their efficiency in catching attention.) The second advantage of coincidence of flashes would be to increase greatly the brightness of the tree, making it visible at greater distances.

Geography of Firefly Tree Aggregations

However reasonable the hypothetical rationale of riverbank aggregation and synchronous flashing may appear, it would be optimistic to suppose that observations made over a few evenings have settled major questions of communal behaviour of fireflies—even for the principal Thai species which we studied. For example, the basic postulate of mating in the trees still requires confirmation, as also do the proposed flights of male and female.

First-hand accounts of mass synchronism in the Philippines, Malaysia, New Guinea, Indonesia, Thailand, Burma and tropical India outnumber those from the rest of the world by thirty to ten[2]. The Oriental displays conform in general to the kind seen in Thailand: huge, long-lasting congregations in riverbank trees, flashing in nearly exact coincidence. Most of the occidental reports involve dispersed populations in flight, active for only short periods, and flashing in waves. The distribution of Oriental-type synchrony corresponds at least roughly with that of Oriental mangrove-nypa swampland, whereas the Western reports are almost all from open terrain.

There is, therefore, reason to regard the congregation of fireflies on trees as being linked to a specific type of topography. However, there is not a single display described in the literature that does not need further critical study of behaviour and habitat in specific relation to mating. Also, many more virgin Oriental swamplands will have to be sampled, as well as comparable areas in Africa and South America, before the nuptial device apparently used by *Pteroptyx* in Thailand can be considered the principal one evolved for coping with swamp conditions[24].

[20] Wynne-Edwards, V. C., in *Animal Dispersion in Relation to Social Behaviour* (1962) has discussed firefly synchronism as a type of conventionalized "epideictic" display or social aggregation aimed basically at population regulation rather than maximizing mating opportunity. If so, the firefly example would be unusual in being apparently a more or less steady-state affair rather than being confined to a breeding season. However, much more study of possible size limitation and spacing of swarms will be required before this interesting suggestion can be assessed.

[23] We thank the late Mr. F. A. McDermott for identifying our fireflies.

[24] A species of *Colophotia* has been reported to be "the" synchronizing firefly of Thailand (Reinking, O. A., *Science*, **53**, 485; 1921) and we have also seen a large sample of *Luciola brahmina*, said to have been collected in the spring along the Chao Phraya River, and also supposed to have been flashing synchronously. Observational errors may well be involved in both reports, but the possibility of more than one synchronizing firefly species in the same area raises some very interesting questions and cautions against generalizations from limited geographical and seasonal experience.

For the convenience of readers, the following extracts are reprinted from Dr. Buck's communication "Flashing of Fireflies in Jamaica" (*Nature*, May 8, 1937, and ref. 9 above):

"DURING the past summer, the members of the Seventh Botanical Expedition of the Johns Hopkins University witnessed displays of firefly activity in the British West Indies as spectacular in their way as any reported from the Orient.

"In front of the expedition's laboratory at Chestervale, in the Blue Mountains of Jamaica, there was a thatch palm which bore below its whorl of leaves an inflorescence a metre in diameter. For about a week in June, and again a month later, this inflorescence was transformed nightly into a sphere of seething flame by the flashes of thousands of fireflies which gathered there. Later, other displays were discovered, particularly on two large acacia trees overhanging the Clyde Valley which harboured such prodigious swarms of fireflies that the nebulous glow was visible half a mile away.

"All the fireflies on these trees were of one species, *Photinus pallens*, and the females outnumbered the males in the ratio of 4 : 3. Each firefly flashed regularly about twice a second while walking along the twigs, and entirely independently of any other individual. There was no sign of synchronism or of response between any individuals or between different trees. The flashing was not inhibited by heavy rain, by lightning, or by the beam of a powerful flashlight, but did not occur on moonlight nights.

"Whatever the cause of the aggregation, it serves an important function in bringing the sexes together for mating, and many coupling pairs were observed on the palm tendrils. The mating, however, appears to be due entirely to accidental contact of the sexes during their peregrinations on the branches. The aggregation habit thus seems to take the place of the accurate systems of flashing signals which serve to bring male and female together in some species of firefly."

BOOK REVIEWS

REMAINS OF THE REVOLUTION

Industrial Archaeology

An Introduction. By Kenneth Hudson. (University Paperbacks.) Pp. 183+59 plates. (London: Methuen and Co., Ltd., 1965.) 18*s*. net.

THE term "industrial archaeology" is little more than ten years old, yet the ideas behind it and the activities associated with it have acquired a remarkable popularity. Mr. Hudson's handbook, first published in 1963 and now appearing in a paperback edition, is a useful and interesting guide, which also includes a bibliography and a gazetteer. The last important chapter on the documentation and recording of industrial archaeology is of great practical value in itself.

The first chapter, on "What is Industrial Archaeology?", is somewhat over-preoccupied with terminology. Clearly industrial archaeology, as it has developed, is not so much a "subject" as a "field". Many of its practitioners would have got by in the past as economic and social historians, and large sections of subsequent chapters are straight economic and social history. At the same time, the term includes the history of technology—still a neglected subject and one which is certainly not exclusively dependent on an archaeological approach—and a sizable element both of architectural history (particularly the history of the "functional" tradition) and of historical geography. It also pulls together the work of railway and canal historians—a well-established and flourishing body—and of people interested in "houses" ("furniture historians" are a more recent group). Yet another element incorporated into the term is "pictorial history" of the kind developed so imaginatively by Hoskins and his school, although "archaeology" is only one side of this, and interest in industry—at least so far as Hoskins's own work is concerned—is only one aspect of an extended and more systematic interest in local history, examining landscape and environment as much as "things".

Hudson is anxious that "industrial archaeology" should be treated as a "subject" rather than that an archaeological approach should be used along with other approaches in inter-disciplinary work on the history (including the recent history) of industry. His healthy enthusiasm seems to me to lead him astray at this point, and he tilts at too many windmills. Who are the "economists, historians and archaeologists" who denigrate industrial archaeology "partly for reasons of sheer conservatism, partly from resentment against an upstart"? As for those who have "serious and genuine doubts that industrial archaeology can be made into a satisfactory academic discipline", one at least is more worried about what the term "a satisfactory academic discipline" means than about the name "industrial archaeology" which, so long as it attracts added interest and stimulates more thorough scholarship, is at least as good as any other term.

There seem to be various reasons for the very genuine interest. Britain's industrial past is being re-scrutinized from many angles, in the middle of the twentieth century, and references to the "industrial revolution" are becoming as frequent and as varied as American references have long been to the Wild West or to the "open frontier". Some critics have detected nostalgia in this, others the search for myth: at a more mundane level, the interest in old steam engines may be not all that different from an interest in vintage cars. It is not only the character or the range of the field, however, which attracts. The method itself—getting outside and around, digging (where relevant), measuring, photographing, keeping logs and record cards—is a source of attraction: it is a method which lends itself also to group activity, and it is not surprising that the growth of interest has been associated with extra-mural education. Some practitioners—and many of their friends and well-wishers—have also been inspired by a sense of urgency. "Things" are being rapidly destroyed—the theme of Hudson's second chapter. Can they be kept or, if they are not kept, can a full record of them be made? Hudson is a forceful and persuasive advocate of realistic proposals to "protect" Britain's industrial legacy, and he catalogues the various attempts already being made to maintain and develop records and to prevent both neglect and total destruction. His book is in places a manifesto as much as a handbook, and he is particularly and rightly concerned to get his "message" over to industrial firms. He quotes with approval, for example, an article by Maurice Barley in the *Journal of British Industry*, a publication where one would hope the lesson would strike home: "Only the most enlightened management realises that to preserve specimens of past machinery and products may create prestige, rather than damage the image of industrial enterprise".

Seven of the eleven chapters deal with particular aspects of the industrial legacy—a general background chapter on "the pace and pattern of the industrial revolution" and chapters (of varying length and depth) on coal and metals; power; textiles, pottery, glass, brewing and distilling (an oddly assorted group); railways, inland waterways and roads; building materials; and farm buildings. He does not have space to go into detail about disappearing evidence relating to more recent technology, although he has a section on cement and two interesting pictures (supplied by Shell-Mex and B.P., Ltd.) of a nineteenth-century "petrol filling point" (not located) and the oldest surviving railway tank wagon for petroleum, now kept at the Museum of British Transport, Clapham. Certain aspects of post-industrial revolution technology, to use conventional terminology, are of immense interest, and when archaeological methods are relevant or necessary to their study they should be encouraged and developed. Knowledge of the present shifting into the future is invaluable in this context. Just as Marc Bloch said that the master gift of the historian was to understand the living and that if you could not understand the living you could not understand the dead, so the most interesting "industrial archaeology" will be that which throws light on past technologies or on past societies so that both the technologies and the societies "live" again. In these terms, the archaeological approach is clearly relevant to much else which is modern besides industry. Urban studies are also beginning to boom, and there is ample scope for an archaeology of the Victorian city. The difficulty and fascination always come from the intelligent relating of the archaeological approach to other approaches. Very seldom do we have to rely on archaeological evidence alone.

For all other kinds of evidence and for understanding the relationships between the different kinds, industrial archaeologists, like others, will still have to rely on historians, historians with no qualifying adjective.

ASA BRIGGS

WILD NATURE

Conservation of Natural Resources

Edited by Guy-Harold Smith. Third edition. Pp. xi+533. (New York and London: John Wiley and Sons, Inc., 1965.) 75*s*.

RAYMOND DASMANN'S *Environmental Conservation* (1960) is probably the most useful text-book yet available on resource conservation viewed ecologically. Although concerned in the main with American situations, Dasmann's wide coverage provides not only a satisfactory basic appraisal of the subject for students—in a form suitable for elaboration by teachers—but also it presents clearly and concisely a readily understandable introduction to conservation acceptable to the general reader.

Guy-Harold Smith's *Conservation of Natural Resources* is concerned entirely with the United States. It is another, but very different, text, the usefulness of which for reference is well established. The first edition was published in 1950, the second appeared in 1958, and now we have this third and largely re-written edition of 1965. Both because its facts and figures have once again been brought almost entirely up to date and because it has sought to keep abreast of advances in conservation thinking and application, it will undoubtedly in the United States be a helpful complement to *Environmental Conservation* for university purposes. In Britain, however, it will be used mainly as a source of reliable factual information, and for an understanding of the American approach.

The book comprises twenty-three chapters, written by nineteen authorities, almost all of whom are university professors; it is arranged in eight parts. The first deals with conservation in the United States, with the public domain, and with economics and conservation; the second is concerned with soils, soil use and soil conservation, irrigation and wetland reclamation, grassland resources and agricultural land use. The five succeeding sections cover a variety of aspects of forest, water, mineral, wildlife and recreational resources, and the conservation of man; the final part summarizes the situation with regard to state and local planning, and national planning and the conservation of resources. There are numerous photographs, figures, tables and maps interspersed in the text, and each chapter is amply referenced. There is an adequate index.

Because of its immediate relevance to the situation in Britain, and perhaps particularly in Scotland, the following extract from the chapter on recreational resources may be quoted: "There are great opportunities for greater public use of private land for recreation. After all, more than two thirds of all land in the United States is privately owned and much of it has a large recreation potential. The large amount of the probable future demand for outdoor recreation makes it probable that public areas will not expand fast enough to satisfy the demand. Recreation could well develop as the dominant use for some private areas or as one use among several on larger areas". Partly militating against such development in the United States, as also in Britain, is the fact that so many public recreation areas are open without charge or for a very low fee. "Although the private providers often charge primarily for the service they render, rather than for their resources as such, the competition from public areas is certainly a factor. The American public, or at least a large part of it, has become accustomed to free or low-cost outdoor recreation and does not realize the value of the resources it so obtains." Surely, there is food for thought here.

Although it is entirely laudable that in a book of this nature controversies should be neither ignored nor dramatized, it is nevertheless remarkable that nowhere in it is there any reference either to Rachel Carson or to Robert L. Rudd's *Pesticides and the Living Landscape* (1964). It is notable that the word 'pesticides' occurs only once, coupled with 'insecticides'. The latter word has four index references but only twice in the text and in one caption is there any mention—and that, as it were, in passing—of the threats inherent, in the form of side-effects, in the widespread use of so many persistent killer chemicals—leading to accumulations of toxic levels.

W. J. EGGELING

A SUMMARY OF BEGINNINGS

Cybernetics and Development

By Michael J. Apter. (International Series of Monographs in Pure and Applied Biology. Division: Zoology, Vol. 29.) Pp. xi+188. (London and New York: Pergamon Press, Ltd., 1966.) 50*s*. net.

BIOLOGISTS interested in the theory of development have, in the past few years, had their expectations raised by the news that the physical and mathematical sciences are developing new bodies of theory concerned with processes of control and organization. These go under a variety of names, such as systems theory, information theory and the like; perhaps "cybernetics" is the most generally accepted way of referring to the whole range of these new developments.

Dr. Apter's short monograph is a summary of these recent developments in so far as they have been applied, or seem capable of application, to problems of biological development. In it can be found short accounts of most of the recent cybernetical work in this field, such as Turing's work on patterns, the application of the Turing machine to macromolecular processing by Stahl and Goheen, Maruyama's and Ulam's work on the algorithmic generation of patterns, Goldacre's model in terms of electrical circuits, discussions by Ashby, Pask, von Neumann and many others. This makes the work a valuable source-book for what might be called "new-fangled" approaches to developmental theory. As such it is to be welcomed and has a place on the shelves of anyone interested in theoretical biology.

The sceptical biologist is, however, likely to ask just what these new mathematical approaches really amount to. Have they produced definitely proved theorems and, if so, can these theorems be applied to biological entities? One is not very encouraged by some of the franker remarks in Apter's book. On page 2 we read: "It is difficult to say what cybernetics is. . . . There appear to be genuine differences of opinion among cyberneticians themselves as to what cybernetics is and what it should be". Or again, on page 71, "A developing system is closed to information, although not of course to energy, . . . (of course energy can also be said to possess information; indeed, information can be referred to almost anything . . .)".

The biologist, accustomed for a long time to analysing organisms into cells and such concepts as stimulus and response, knows already something of the weaknesses as well as the strengths of such an approach. When confronted with a mathematician who talks impressively about "axiomatization" which "means this: we assume that the elements have certain well defined, outside, functional characteristics; that is, they are to be treated as 'black boxes' ", he is tempted to reply: "Yes, fine, as far as it goes but now go on and say something new". After all, what Apter calls "Wiener's major insight that organisms can be discussed . . . in terms of 'homeostasis' and 'negative feedback' " had actually been applied by embryologists to developmental processes long before Weiner appeared on the scene; for example in ideas of the canalization of development. What one hopes for from the mathematicians is a clear-cut body of theory about the manner in which the individual processes are organized so as to result in homeostatic systems. Such a body of theory certainly exists in certain special systems,

such as electrical circuits, but does it exist in relation to the fundamental processes of embryonic development, such as gene activation, protein synthesis and the like? If it does, I do not think that any cybernetician has yet expressed it in a way that makes its relevance to embryology clear. Certainly Apter does not do so. His book is a summary of beginnings which always seem to be promising to lead to something important but have, as yet, scarcely done so. C. H. WADDINGTON

TREES IN BORNEO

Manual of the Dipterocarp Trees of Brunei State

By P. S. Ashton. Pp. xii+242+58 plates. (London: Oxford University Press, 1964.) 63*s*. net.

ONE of the major economic products of Borneo is timber, and this is largely produced by trees belonging to the family Dipterocarpaceae. It is therefore of considerable importance that this group should be well studied taxonomically. Many of the trees concerned are forest giants some 150–200 ft. high, so any taxonomic work based solely on herbarium specimens (often accompanied by inadequate field-notes) is obviously likely to be unsatisfactory. This applies especially to the Dipterocarpaceae, where considerable variation occurs between the vegetative characters of juvenile and mature leaves, and consequently a lack of suitable field-experience has led to misinterpretations of the differences between herbarium specimens, thus leading to wrong taxonomic decisions. The ideal circumstances for a taxonomist working on this group is for him to have first-hand knowledge of all the species in the field. This ideal has been achieved by Dr. Ashton in his investigations of the Dipterocarpaceae of Brunei. The major geographical centre of this family is Borneo, where more than half the species occur. Therefore, in spite of the small size of the State of Brunei the number of species which occur there is more than 150, which is just about the number of those which occur in the much larger area of Malaya. Nine genera are represented in Brunei, the largest being *Shorea* with 75 species; *Dipterocarpus*, *Hopea* and *Vatica* each have 20 or more species. Dr. Ashton was able to examine a total of some 1,500 Dipterocarp collections from Brunei, nearly half of which he collected himself. All this, in addition to his thorough knowledge of the trees themselves and their ecology, has provided the secure foundation of this excellent book. Its main purpose, as stated by the author, is to provide foresters with a work which will enable them to recognize all the species in the field, thus leading to a stable vernacular and trade terminology. This manual, furthermore, is intended as a basis for a complete revision of Bornean Dipterocarps.

Field-keys and systematic keys are provided both to the genera or main field-groups and to the species. The systematic keys include flower and fruit characters. As Symington's *Foresters Manual of Dipterocarps* is still widely used in Brunei and comprehensive generic descriptions were provided in it, these have not been repeated in this new publication, but full diagnostic characters of the genera are provided. The treatment of each species gives the synonymy, vernacular names, separate field and herbarium descriptions as well as notes on uses, distribution and regeneration. Herbarium specimens are also cited. The herbarium descriptions are very full and give much useful detail including seedling and sapling characters. Many of the species are illustrated by line-drawings of the leaves and fruits; there are also many photographs of trees, showing especially the appearance of their bark. In view of the number and diversity of species of *Shorea* involved, this genus receives a somewhat different treatment. Nine sections are recognized and some of these are further subdivided. The systematic key includes all the species occurring in Brunei. The treatment of the species is divided up into the four field-groups, each provided with a separate field-key; the species in each field-group are numbered separately, which is a disadvantage to the taxonomist, who will want to use this book as well as the forester. (The species in the complete systematic key are unnumbered.) It is noteworthy that although *S. albida* belongs to section *Anthoshorea*, which constitutes the White Meranti field-group, on gross field-characters it is a Red Meranti. A similar situation occurs in *Hopea*, where there are both four botanical groups and four field-groups, but these do not entirely correspond with one another.

Although intended primarily for foresters, the keys and detailed descriptions will also make this work most useful to taxonomists. This important book, which has been printed in Singapore, has been attractively and well produced. L. L. FORMAN

GRASSHOPPERS IN RUSSIA

Locusts and Grasshoppers (Catantopinae)

By L. L. Mishchenko. (Fauna of the U.S.S.R.: Orthoptera, Vol. 4, No. 2.) Translated from the Russian by B. Munitz. Pp. xii+560. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 135*s*.

A TAXONOMIC work published in 1952 and translated 14 years later cannot be expected to provide up-to-date information on the fauna of large parts of two continents, but its English version will be welcomed by specialists in this group of insects. They should, however, bear in mind the somewhat vague definition of the area covered, the author merely saying that he disregarded "species inhabiting western Europe, the Mediterranean region, southern Iran, Afghanistan, India, China and Japan, which are not found in U.S.S.R.". These limitations, moreover, are applied inconsistently, since the book includes the Mediterranean *Trapidopola longicornis*, *Pezotettix anatolica*, *Sphenophyme rugulosa* (and even a new subspecies of *Miramella* from Albania), Tibetan genera *Indopodisma* and *Kingdonella*, Indian *Pachyacris* and *Patanga*, some species from southern Iran and *Fruhstoferiola* of south-east China. This would be less objectionable, were it not that other genera and species from the same areas are omitted; thus, several species of *Kabulia* from Quetta are left out, but a *Conophyma* from that locality is included; two species of *Dericorys* from Baluchistan are in the book, but a third is not. two Iranian genera, *Lyrotylus* and *Dabba*, are mentioned in an introductory chapter, but ignored in the text.

The introductory chapters dealing with the morphology, development and ecology of Acrididae are brief. Anatomy is not even mentioned, except for a rough sketch of the male copulatory apparatus of *Conophyma*; this character has been used by taxonomists long before 1952, but it is ignored in keys and descriptions. A fairly long chapter deals with the geographical distribution of Catantopinae, but mainly in the form of long lists of tribes (illustrated by maps) and genera supposed to be characteristic of various regions; the fauna of the Palaearctic region and of the U.S.S.R. are dealt with in more detail, but in the same uninspired manner.

The bibliography is in two parts—papers in Russian, with their titles both transliterated and translated, and those in other languages.

The classification is still that of Brunner–Wattenwyl (1893), with a few recent modifications, but the author himself has introduced hardly any improvements. His main original contribution is a key to small apterous grasshoppers of the genus *Conophyma*. This is represented by sixty-eight species in the high mountains of Central Asia providing a remarkable example of speciation by isolation; most of the species have been described by 'Mishchenko' himself. They alone make up half the

section on U.S.S.R. fauna, which comprises 126 species of Catantopinae; the remaining 107 species dealt with in the book are from adjoining countries.

The initiative of the Israel Program for Scientific Translations is very welcome, but much greater care is essential in translating and editing highly specialized books than has been shown in this case. To begin with, the author's name is transliterated by himself in a paper published abroad (reference on page 50) as Mistshenko, not Mishchenko. When the English text is compared with the original, serious mistranslations can be found, such as "exoskeleton" instead of "armature" (page 10); tribe Podismini is "divided" into several genera, when the original says that it was considered to consist of a single genus *Podisma* (page 32). In the original it is said that there are no endemic forms in western Siberia, while there are many in the eastern, but the translation reads "In Siberia endemic forms are conspicuously absent" (page 35). In some cases the translator has invented new words, like "xerothermation" and "multiformity". Most ludicrous are his attempts to translate, instead of transliterating, popular Russian names for the insects. The Russian name for grasshopper is *Kobylka* which literally means "filly", in allusion to the resemblance of the head profile to that of a horse; the translator, following the dictionary, renders the name *polyarnaya kobylka* as "polar young mare grasshopper"; what is, in Russian, a "tree grasshopper" becomes "wooden young mare grasshopper". For some of these faults the responsibility falls on the editor who, although a specialist taxonomist, apparently had no knowledge of the original language; bilingual specialists in this group exist in Israel.

A very strange feature of the book is that the indexes at the end give references to the pages in the Russian edition (inserted on the margins of pages of the translation); this is mentioned, but in very small type, in a footnote, so that readers are likely to suffer annoyance before they discover the secret. The price of the book, even at present rates, is very high. BORIS UVAROV

REGULATION OF ADRENAL FUNCTION

The Neuroendocrine Control of Adaptation

By K. Lissák and E. Endröczi. (International Series of Monographs in Pure and Applied Biology. Division: Modern Trends in Physiological Sciences, Vol. 25.) Pp. xii+180. (London and New York: Pergamon Press, Ltd., 1965.) 70*s*. net.

THE main aim of *The Neuroendocrine Control of Adaptation* is to provide an account of the way in which the central nervous system controls the endocrine organs, and in particular the adrenal glands, concerned with the adaptation of the animal to its environment. The subject-matter may be divided into two main sections. The first half of the book deals with the regulation of the secretion of adrenocortical hormones by the pituitary, and in the second part the control of the production of adrenocorticotrophic hormone by the hypothalamus is discussed. Sections are also included on adrenocortical regulation during development and in relation to gonadal function.

This book was originally published in 1960 under the title *Die neuroendokrine Steuerung der Adaptationstätigkeit* by Verlag der Ungarischen Akademie der Wissenschaften, Budapest. The present edition, which is in English, represents a slightly revised version of the original work. However, the literature survey has not been brought up to date and the majority of the references quoted were published before 1960. For this reason, no account can be taken of the recent work in the general area of neuroendocrinology, much of which is germane to the subject-matter considered. Thus, recent studies involving the corticotrophin releasing factor, the use of synthetic adrenocorticotrophic hormone preparations, and new techniques for the estimation of adrenocorticotrophic hormone and of corticosteroids and their metabolites are not discussed. The book is therefore of little value in providing an up-to-date account of neuroendocrinology to workers in this field. However, a proportion of the references quoted are taken from journals such as the *Acta Physiologica* of the Hungarian Academy of Science and the *Bulletin* of the U.S.S.R. Academy of Science. Because of this, the international coverage of literature published between 1950 and 1960 which is presented is likely to be of value to investigators who do not normally have access to Eastern European and Russian journals.

In their survey of published work, the authors have in many instances presented conflicting results. Unfortunately, an assessment of the relative merits of the data described is not always given. It is therefore likely that a reader who has only a general knowledge of endocrinology may find this book rather indecisive. Summaries of the contents of each chapter are not provided and, particularly in the latter half of the book, subheadings in individual chapters have not been used. This means that, in order to use the book as a reference work, extensive use must be made of the subject index. However, this is unduly short, comprising only 2 per cent of the length of the book, while the index of authors represents 7 per cent. Two of the main omissions in the subject index are the absence of any reference to steroid hormones, such as hydrocortisone and corticosterone, referred to in Chapters 2 and 3, and to various animal species used in the experiments described in the second half of the book.

In spite of its limitations, this book is likely to be a useful addition to departmental rather than to general libraries. The main aims are certainly achieved and in particular a fairly readable account of some of the historical aspects of the subject is provided. Experiments in various animal species, as well as in humans, are described and care is taken to indicate the species differences which may occur in the study of the interrelationship between the hypothalamus, pituitary and adrenal glands. The book, which is printed on paper of high quality, is well laid out and the tables and diagrams are generally clearly presented. E. TREVOR BELL

ZONE ELECTROPHORESIS

Methods in Zone Electrophoresis

By John R. Sargent. Pp. 107. (Poole, Dorset: The British Drug Houses, Ltd., 1965.) 8*s*. 6*d*.

ZONE electrophoresis is a method extensively used for the investigation of substances of biological importance, but the worker is frequently faced with the problem of knowing the forms and conditions available and of evaluating which of them is the most suited for his particular problem. This book is therefore greatly to be welcomed, as it provides us with a much needed and up-to-date book covering with full working details the whole range of materials and conditions available for zone electrophoresis.

The book opens with a short chapter on general theoretical considerations and this is followed by chapters on electrophoresis on paper (low and high voltage), cellulose acetate, starch gel, agar gel and polyacrylamide. There is a chapter on block electrophoresis and the book closes with a useful section on the choice of media. The great merit of the book is that the abundance of information given is presented in an extremely concise manner and is divided into appropriate sections enabling details to be found at a glance. For example, for each medium discussed there is a description of the procedure, the types of apparatus which may be used, a selection of suitable

buffers and full details of staining for each type of substance. Where applicable, the author has described separately conditions for the electrophoresis of different classes of substances, such as proteins, amino-acids, carbohydrates and nucleotides. Although an empirical approach must generally be taken in establishing the best conditions for the analysis of a particular mixture of substances, especially with proteins, the author does suggest how this may best be done. There are numerous diagrams and plates to illustrate details of apparatus and types of pattern obtained, and a full bibliography is given for each method. It is perhaps unfortunate that there was a long delay in publishing (the bibliography extends only to September 1963) with the result that some developments before publication were excluded. Thus, there is only a brief mention of the thin-layer methods which are valuable in conjunction with chromatography for obtaining "fingerprints" of peptides. However, techniques used for proteins, carbohydrates and amino-acids have undergone relatively little modification since the book was prepared.

While the author points out some of the problems that arise in the interpretation of results, his book is essentially concerned with the practical aspects of the subjects and as such will be of great value not only to the novice but also to the experienced worker in this field.

E. R. SKINNER

NOT A HANDBOOK

Semiconductor Junctions and Devices

Theory and Practice. By William B. Burford, III, and H. Grey Verner. Pp. xx+328. (New York: McGraw-Hill Book Company, Inc.; Maidenhead: McGraw-Hill Publishing Company, Ltd., 1965.) $12; 96*s*.

DURING the period 1950–60, when developments in semiconductor devices were rapid and often entirely novel, books on the subject quickly became, in part at least, out of date. There was, indeed, the risk that everyone interested in the devices would become so accustomed to frequent and major changes that they would continue to see them, potentially at least, in every small development. But although the effort devoted to research and development on the design, technology, characterization and applications of the devices continued to expand, the years since 1960 have been marked much more by evolution and consolidation, as witness much of the work on integrated circuits, which leans so heavily on the basic planar techniques. Important advances have still been made, such as the insulated-gate field effect transistor, the semiconductor laser and the Gunn effect oscillator, but these devices have supplemented rather than displaced earlier types.

Some consolidation must be welcomed by authors and teachers, for it will allow time to assess the relative importance of different parts of the subject, both in academic and industrial terms. It presents an opportunity for attempting the writing of a handbook which could be widely accepted for a few years. The subject has certainly become so big, both in coverage and in the number of scientists, technologists and engineers engaged in it, to offer enough incentive for several such attempts. Even if the subject were to break loose at its roots again, the time constant for large-scale industrial change has now lengthened to several years; new ideas must show a very clear-cut advantage in some important feature, while matching older ideas in other respects, before being quickly adopted.

Mention of a handbook here is misleading, for this book cannot be considered as such despite the claims of the publisher that it is a "comprehensive modern survey" whose pages of "hard-packed logically arranged information cover everything from general principles . . . to specialized processes of two-junction transistor synthesis". The authors are, however, more realistic as to the purpose of the book and its likely use. It is based on a teaching course, of considerable coverage, but was largely written during 1960–1 with re-editing during 1963. It seeks to cut across the boundaries separating university disciplines, in order to bring together physicists, electrical engineers and materials scientists, but it makes many concessions in doing so; anyone with a basic training in a sub-division of the subject will find some sections unduly elementary.

The order of presentation is sensible, with the first eight chapters running through the physical principles underlying junction behaviour to the structure and performance of devices with one, two or more junctions. Serious analysis or abstract ideas are restricted to a chapter on Fermi statistics; otherwise the writing is largely descriptive and will present no difficulties to engineers who are not mathematically minded. Some basic ideas are not, however, put over very well. In particular, the finite lifetime of minority carriers is insufficiently emphasized and the capacitance of a biased junction is based on Q/V rather than dQ/dV; the transport of carriers across the base region of a transistor, and the dependence of carrier density on position in that region, are not sufficiently explained.

The next four chapters describe, in a very elementary way, applications of transistors to amplifiers, generally using the simplest of equivalent circuits; they do not provide a basis for circuit design. The next chapter, on commercial transistor specifications, looks at first sight to be quite out of logical order, even assuming it has any place at all in the book. However, it is a serious attempt to explain to newcomers how device manufacturers express ratings and performance, but the parameters prominent in the previous chapters are largely missing. A descriptive chapter on switching applications follows. It is out of touch with modern practice and ignores both the classic analysis of Ebers and Moll and the charge control approach of Beaufoy and Sparkes. From this point onwards the book degenerates into a collection of descriptions, sometimes of devices long relegated to near oblivion; the commentary lacks any critical element. A chapter on metal-semiconductor contacts recognizes that these often form part of devices and makes the reader aware of the complications they can introduce, but the following chapter on point contact devices has little value to-day. The final chapter is largely devoted to device reliability, and the authors have usefully covered much ground in about twenty pages; the data they present may now be far from representative, but illustrate the subject adequately.

It is, frankly, difficult to see for whom, and for how long, this book will be a primary guide. It needs modernizing, much condensing and a sharpening up if it is to be even a substitute for the handbook which someone must surely by now be attempting.

J. R. TILLMAN

Annual Review of Nuclear Science

Vol. 15. Edited by Emilio Segrè, in association with Gerhart Friedlander and H. Pierre Noyes. Pp. 502. (Palo Alto, California: Annual Reviews, Inc., 1965.) $8.50.

OVER the years, the *Annual Review of Nuclear Science* has established a pattern of authoritative and up-to-date review articles, about half of which are on nuclear physics while the remainder range over the whole wide field embraced by the term 'nuclear science'. Volume 15 is no exception With such diversity, a reviewer can serve little purpose beyond indicating the subjects covered so that the reader can decide what may be in the mixture for him.

Probably the most noteworthy, and certainly the longest, article is that by Lee and Wu on weak interactions. This volume contains only the first part of the full review and

includes a comprehensive survey of the theory and that part of the section on experiments and phenomenological analysis covering β-decay, μ-decay, μ-capture and π-decay. The leptonic and non-leptonic decay of kaons and hyperons and parity-violating reactions will be included in next year's instalment. Other articles primarily of interest to those concerned with nuclear physics are those on photonuclear reactions, by Danos and Fuller; on the measurement of the masses of particles which undergo weak and electromagnetic decay and also of the mass of the antiproton, by Barkas; on non-spherical nuclei, by Rogers; on reactions between complex nuclei, by Greider; and on spin and parity determination of elementary particles, by Tripp.

Articles of more general interest are by Fleischer, Price and Walker, on particle track formation in solids and the use of solid-state detectors in nuclear science and geophysics; by Harbottle, on the chemical effects of nuclear transformations in inorganic solids; by Hart, on the radiation chemistry of aqueous solutions; by Blomeke and Roberts, on radioactive waste management, particularly that associated with reactor fuel processing; by Comar, on the movement of fallout radionuclides through the biosphere and man; and by Mole, on dose response relationships in mammalian radiobiology. J. E. TERRY

Information and Communication Theory

By A. M. Rosie. (Electronic User Series.) Pp. xii+175. (London and Glasgow: Blackie and Son, Ltd., 1966.) 32*s*. 6*d*. net.

THIS volume is one in a series ostensibly written for "qualified scientists and engineers for whom electronics is a fringe activity". The text is based on lectures given in final-year and postgraduate courses in a school of electrical engineering and is, therefore, potentially useful to those for whom electronics is much more than a "fringe activity". The author has tried to restrict the range of mathematical ideas used in presenting the theory and in two chapters has given brief introductions to such topics as the Fourier transform and probability theory. Nevertheless, the book is suitable for only two types of reader—those for whom these introductory chapters can serve as revision and those able to absorb new mathematical ideas quickly.

About two-thirds of the book is concerned with developing the ideas of information theory and applying them in the study of communication systems. The material is presented clearly and the examples and illustrations are well chosen. The chapters on "Sources and Channels" and "Ideal Communication Systems" are particularly good and these and two following sections—concerned with engineering applications of the theory—will be useful to undergraduates reading for degrees in electrical engineering.

The final chapter is concerned with the uses of information theory in biology, neurophysiology and psychology and with pattern recognition. This chapter is not up to the standard of the remainder of the text and the problems it attempts to treat cannot be dealt with in the space available. J. T. ALLANSON

The Plastic Methods of Structural Analysis

By B. G. Neal. Second edition. Pp. xiii+358. (London: Science Paperbacks and Chapman and Hall, Ltd., 1965.) 25*s*.

THE Steel Structures Research Committee published its final report on elastic design in 1936, and this date may be taken conveniently as that of the start of three decades of work on plastic theory. In the first decade Sir John Baker investigated simple beams and frames (and applied the findings to the design of the Morrison shelter); this phase closed in 1948, when a clause permitting plastic design of steel structures was inserted in British Standard 449. The second decade saw the formalization of the theoretical basis of the method; the theorems of the mathematical theory of plasticity were applied to the problem of the building frame, and immediate advances were made. For example, the powerful technique of combination of mechanisms was developed, with which Prof. Neal's name is associated. This period closed in 1956 with the publication by Baker *et al.* of *The Steel Skeleton II*; in the same year Neal's book was published (second edition 1963, now reprinted as a paperback). Since 1956 detailed problems of the design of structural elements have been investigated, but the main advance during the past ten years lies perhaps in the slow assimilation of plastic methods into the vocabulary of the designer. Plastic theory offers a completely different way of approaching the structural problem, and it is this new approach which may prove to be of the most lasting importance. Measured against this background, Neal's book betrays that it was first written 10 years ago. The first four chapters, laying the foundations of the theory, are clearly and elegantly written; written to-day, however, the first chapter (on stress distributions) would largely disappear, and virtual work would be introduced earlier than Chapter 3. The four chapters forming the second half of the book deal with particular topics such as deflexions, minimum weight design, and shakedown, this last reflecting one of Prof. Neal's own research interests. The book as a whole gives the impression of being slightly old-fashioned; the first half is not quite incisive enough in its treatment of the basic theory, and the second is too detailed in its treatment of topics which are seen now to be not of prime importance. Overall, however, the book is probably still the best introduction a student could have to the plastic design of steel frames.

The Habit of Authority

Paternalism in British History. By A. P. Thornton. Pp. 402. (London: George Allen and Unwin, Ltd., 1966.) 45*s*. net.

IN spite of an early reference to William Whewell, Prof. Thornton's study of paternalism in British history comes no nearer than Prof. Hogben's *Science in Authority* to examining the rival claims of authority and of intellectual initiative. The book might be described as an exposition of Governor Morris's observation to Washington that the exercise of authority depends on personal character, but while Prof. Thornton seems to accept the view that expertise of any kind is ancillary to the tradition of authority and in itself gives none, he never urges the scientist to accept office and is little concerned with how the scientist or other expert can qualify himself to exercise leadership or authority. To that extent the book disappoints, and it lacks the interest for the scientist or technologist that its opening might suggest. Prof. Thornton describes with perspicuity and candour the tradition of successful paternalism which characterizes British history, and the pragmatism which pervades the book suggests that Prof. Thornton himself is well qualified to expand this into a badly needed analysis of the personal aspects of the place of the scientist in the task of government. That task is not attempted: there are occasional pointers or warnings but it is left to the scientist himself to make the analysis. Accordingly, while the book is entertaining as well as instructive, its scientific interest is slight. The title alone points to the existence of a problem central and inescapable for our times, whether we approach it primarily from the political side or from the kind of consideration which prompted Prof. R. S. Kuhn to discuss the structure of scientific revolutions. Nevertheless, in these seven chapters, discussing in succession what Prof. Thornton terms the colonization of England, the Estates of the realm, English authority overseas, the dislocation of society, the survival of the ascendancy, Bonar Law's dynasty, and agents and patients, any one who attempts that task will find much that is instructive and suggestive. R. BRIGHTMAN

MEETINGS

MATHEMATICAL ASSOCIATION—1966

THE annual conference of the Mathematical Association was held in the University of Keele during April 13–16.

During the business meeting it was made clear that the Association, now with more than 6,000 members, is playing a full part in the present development of mathematical education in Britain and in the world as a whole: this has been achieved at no small cost to the Association, as the deficit of £3,000 on the year's working shows. Worthy of special comment is the fact, however, that members of the Association are anxious not only that the work should continue but also that it should be extended at additional cost to themselves, including an increased subscription.

Mr. J. T. Combridge, reporting generally on "Current Affairs", referred to the recent report of the Joint Mathematical Council on *In-Service Training for Teachers of Mathematics and Science*. It appears that mathematics is the only discipline which has put forward a blueprint indicating the costs of schemes for such training with its emphasis on local (school-based) mathematics centres. The Schools and Industry Committee of the Association continues to be influential and the part played by the Association in this field is recognized by and supported by other members of the Joint Mathematical Council. Of the Association's work in the past few years, Mr. Combridge said that the Association had followed its proper course, which is not one of sovereignty or slavery, but one of service: indicative of this was the support given by the Association to the Joint Mathematical Council and the Institute of Mathematics and Its Applications and the influence of members of the Association in many of the newer teaching projects. The meeting approved a change of rule which will allow overseas mathematical associations to become affiliated to the Mathematical Association. Such associations will continue to enjoy the facilities of the *Gazette* and other publications of the Association, but will also be assisted by an interchange of literature, thereby encouraging the development of such associations.

In her presidential address, Mrs. E. M. Williams, formerly principal of Whitelands College of Education, commented that it was only the fourth time a woman had been president of the Association, and recalled that in the more limited conditions of the nineteenth century at least two women demonstrated that new mathematical thinking was not alien to the feminine mind. Before the century closed, Maria Edgeworth at the beginning of the century and Mary Boole (wife of the founder of Boolean algebra) were foreshadowing some of the modern developments in the teaching of mathematics. Maria had given a hint of the concept of a set and recommended an approach through the handling of cubes; Mary had emphasized the logical basis of arithmetic as it should be taught to children and recommended the use of non-numerical situations to bring out the logical structures. Mrs. Williams considered that there were grounds for present optimism in the evidence of the lively interest among women teachers, particularly those in primary schools, in the more logical and structural approach to mathematics. Among all pupils there was a preference either for the kind of mathematics that could be seen to be useful or for those forms that gave satisfying patterns of thinking. In primary school experiments now being carried out it was recognized that children's own investigations were the material from which mental images and logical thinking emerged. The important task for a teacher was to lead pupils on from the intuitions derived from experience to the mental patterns which enabled them to understand the world around and to solve problems that occurred in new situations. If mathematics is supposed to concern patterns, structures and the building up of visual and symbolic imagery, varied practical experiences must be provided from which pupils can develop the power to relate the mental images with which their minds are stored. The essential role of mathematics for children in general seems to be the provision of a store of patterns of form and thought which enable an individual to recognize and to respond effectively to the scientific, aesthetic and social relations discoverable in their surroundings.

The Mathematical Association, with its 95 years of fostering improvements in the teaching of mathematics, had done much to help the present movement at home and overseas and will continue to do so. Mrs. Williams emphasized that the fact that the re-appraisal of school mathematics was world-wide drew attention to the nature of the subject itself. It was the outcome of man's systematized thinking during many centuries with contributions from all the great cultures. Through such thinking, developing now with great rapidity, man's scientific mastery continued to grow. New mathematics should represent not a break with the past but an enlargement in scope and depth. In this way mathematics could fulfil its true educational role of enabling each individual to enlarge his capacity for understanding and thinking about his complex world.

The first discussion of the conference was on the Joint Mathematical Council's report on the *In-Service Training for Teachers of Mathematics*, with the chair taken by Prof. W. A. C. Stewart, professor of education, University of Keele, a member of the Schools Council and Vice-Chancellor designate (1967) of the University of Keele. The discussion leaders were Prof. J. Wrigley, professor of education, University of Southampton, Mr. D. G. Crawforth, Dr. Challenor's Grammar School, Amersham, and Mr. W. M. Brookes, Department of Education, University of Southampton, all of whom were members, under Prof. Wrigley's chairmanship, of the working party responsible for drawing up the report on in-service training.

Prof. Stewart, in introducing the speakers, considered that the most pressing and important problem in the teaching of mathematics is that of those who teach and how they equip themselves. Prof. Wrigley described the report as almost inevitable: in this changing world of new syllabuses and new ideas, many of our previous procedures have been found wanting, if the needs of all teachers were to be served. The proposed Local Mathematics Centres have become an urgent necessity. In Prof. Wrigley's view it is imperative that the idea of class teaching as one teacher confined with thirty people should be dispelled. He spoke of much more team teaching, more use of aids, much more co-operation between different sorts of teachers, for example primary and secondary. A vertical interchange of teachers, he considered, was important.

Mr. Crawforth considered that there are a large number of children who are not effectively taught, however conscientious and dedicated the teacher may be. He described the efforts which he and his colleagues in the Amersham school and district have made to overcome this difficulty by the introduction of team teaching. Colleagues became used to working together in the same room and discussing work afterwards. They soon realized the mesh of activity in a conventional classroom situation of which they had previously been unaware or had ignored. The children also came to feel that there was something important to talk about in the mathematics of a situation: in time the children felt free to join the discussion when appropriate. Experienced teachers were discovering for the first time that children could perceive and generate mathematics out of their own awareness and their own strength in a way that had never been conceived possible

previously. Mr. Crawforth acknowledged the difficulties ahead, including the difficulties of head teachers with the many external and internal pressures on them, but said that in his view the children must be put first. The kind of activity which generates a neighbourhood of living and growing teachers in contact with living and growing children holds out the most hopeful prospect for effective mathematics learning that has been evolved so far.

Turning to the quality of the profession, Mr. Brookes, speaking of the present often self-imposed isolation of teachers, felt that, although the numbers of teachers are increasing, the quality is not sufficiently high to keep the mathematical body healthy. We may be faced with a redeployment of our mathematical skills. The present prejudices which exist between work at the levels of the university, the departments of education, the colleges, the schools (primary, modern comprehensive, layered, etc.), must be removed. Isolation will ensure that such prejudices are not removed.

After a useful floor discussion, Prof. Stewart spoke of similar problems to those of mathematics existing for all who are in any way concerned with teaching. He spoke of the complexity of the overall problem and the difficulty of disentangling the complexity to make it in any way manageable and yet of avoiding the setting up of little empires.

Modern Mathematics Projects

The second discussion of the conference dealt with modern mathematics projects, and took the form of a 'brains trust'. The members of the panel were selected as representative of different projects and consisted of Prof. J. D. Weston (University College, Swansea; Swansea Scheme), Mr. D. A. Quadling (Marlborough College; Schools Mathematics Project), Dr. G. Matthews (director, Nuffield Foundation Junior Mathematics Project) and Mr. A. J. Moakes (St. Paul's School; Mathematics in Education and Industry Project), together with Mr. F. J. Budden, Royal Grammar School, Newcastle upon Tyne, who represented the point of view of those not committed to any project or associated with any scheme. The questions ranged over the use of desk calculators, axiomatics, concepts *vis-à-vis* problems, the age for introducing sets, the needs of university science and engineering departments, and the place of group theory in school mathematics. The final question to the team was: "What do the members of the panel expect to find on Mount Ararat when the floods of modern mathematics subside?" The replies were summarized by the President, who likened the problem to the arrival of the ark with its preservation of all the valuable species. She hoped that all the essential mathematical ideas, which have always survived, would still be there on the top of Ararat when the ark has come to rest. But the arrival time was not a period of rest: it was the beginning of a developing culture and this was what could be looked forward to as, from this present stress and excitement, the new ideas were absorbed and, with their refertilization, school mathematics was taken forward along the expanding path of mathematics as a whole.

General Lectures

Prof. A. P. Robertson, professor of mathematics in the University of Keele, speaking on "Mathematics at Keele", said that postgraduate experience showed that Keele students could more than hold their own in the postgraduate field in mathematics, despite the somewhat wider base of their degrees. A questioner from the floor thought that the average of two mathematics graduates per year entering teaching was not a healthy sign. To this Prof. Robertson suggested that school teaching must be made a profession which attracts.

Dr. G. A. Garreau of the City University, London, who is in charge of the Association's Problem Bureau, described the work of the Bureau which mainly deals with problems at the university entrance scholarship level. Prof. E. C. Zeeman, professor of mathematics in the University of Warwick, spoke on "A Topological Theory of the Brain". Mr. G. Edgecombe, of Plymstock Comprehensive School, illustrated his lecture on Moiré Bands with carefully prepared patterns and drawings which illustrated the appearance of these bands in the very simplest of two-dimensional intersections of two sets of straight lines—up to three-dimensional effects. He mentioned many of the materials and conditions which lend themselves to Moiré effects and indicated the requirements which must be satisfied if a definite and strong pattern is to be produced. The final lecture of the conference was on "Gas Bearings: a Mathematical Problem in Engineering", and was given by Dr. M. D. Wood, director of engineering studies in the University of Cambridge. Dr. Wood used his lecture to illustrate how mathematics can and often must be used to solve engineering problems that have proved intractable to an empirical approach; and that engineering is a satisfactory and worth-while career for mathematical specialists from sixth forms.

R. G. Cross

STRONTIUM METABOLISM

The study of strontium metabolism illustrates the axiom that scientific progress creates more problems than it solves. A field of endeavour which was almost unknown 20 years ago is now the scene of persistent and growing effort by workers of diverse interests, including physicians, biochemists, veterinary scientists and physicists in many countries. A symposium was held at Chapelcross, Scotland, during May 5–6, which reviewed a variety of experimental enquiries, illuminating successes and—more often—failures in providing answers to the many important questions made topical by continuing interest in the biological consequences of radioactive fall-out from nuclear explosions, past and future. The symposium was sponsored jointly by the Medical Research Council and the United Kingdom Atomic Energy Authority.

The main areas of discussion were (*a*) the uptake and incorporation into body tissues of radioactive strontium present in food; (*b*) the somatic hazards of radioactive strontium; (*c*) the possibility of modifying the uptake and metabolism of radioactive strontium by the action of drugs. Progress in each of these areas is influenced by the difficulty of measurements based on the strontium-90 which occurs in fall-out.

The somatic hazards of radioactive strontium are difficult to assess because, at present levels of dietary and skeletal contamination, they are so small in relation to the notoriously elusive effects of ionizing radiation from the natural background or even from diagnostic radiology. Extrapolation from animal experiments is uncertain, partly because the dosage levels of strontium-90 commonly used are greater (by a factor of 10^6 or more) than those encountered in the human subject, and partly because of dietary and physiological differences between man and other animals.

The average personal daily intake of strontium-90 in Britain at the present time is about 25 pc. and the total amount of this nuclide contained in the body of a typical adult is no more than 2,000 pc. Because only β-radiation is emitted, it is not possible to obtain a numerical estimate of this contamination by external measurements—or, indeed, by internal measurements either. The investigator who is concerned with the human subject has three possibilities.

First, he may measure the strontium-90 concentration in bone samples obtained *post mortem*. In Britain, about 500 samples are analysed every year and similar programmes are under way in several other countries. Work

of this kind provides the bulk of our information about strontium uptake in children. In studying the processes involved in the passage of strontium-90 from atmospheric dust (or rain) into human bone it is useful also to examine the contamination of milk and other foodstuffs. Simple models allow reasonably accurate prediction (*a*) of dietary levels of strontium-90 and of radiation dose commitment (in terms of fall-out deposition on the ground) and (*b*) of strontium-90 levels in children's bones (in terms of dietary contamination). Using fall-out and dietary measurements, J. F. Loutit (Medical Research Council Radiobiological Research Unit, Harwell) found evidence of rapid turnover of skeletal strontium in childhood. During each of the first 9 years of life, about half of the existing body burden of strontium-90 is apparently lost.

Secondly, it is possible to measure the strontium-90 in urine, thus obtaining an indication of the metabolism of the nuclide in the living subject. At the Chapelcross meeting, Janet M. Warren (Regional Physics Department, Western Regional Hospital Board, Glasgow) reported studies on children in two age groups. In those less than 3 months old, living on an all-milk diet, the concentration of strontium-90 (expressed as pc. strontium-90/g calcium) was about the same in the urine as in the diet. For older children in the age range 2–13 years enjoying a normal mixed diet, the concentration of strontium-90 in the urine was about half the corresponding figure for the diet. C. L. Comar (Cornell University) observed that the ratio of urinary to dietary strontium is correlated with the daily output of calcium in the urine. In general, he advised, it is desirable to obtain data on both elements in simultaneous or parallel experiments. Earlier belief in the close similarity of calcium and strontium metabolism has been modified in the light of more refined experimental evidence now available, but the metabolism of strontium (stable or radioactive) is regulated more markedly by calcium levels in the body than by stable strontium levels.

Thirdly the experimenter may use radioactive isotopes of calcium and strontium in tracer experiments to illuminate metabolic processes. Useful information is still being extracted from an investigation begun at Harwell in 1962, when five adult male volunteers lived for periods of 3 or 4 weeks on a special diet consisting mainly of bread and milk. The bread was made from grain containing a relatively high concentration of strontium-90 and the milk came from a cow which had received an intravenous dose of strontium-85. Measurements of both isotopes were made in urine and faeces; the total retention of strontium-85 was estimated with a whole-body counter.

From this and similar studies it seems that the movement of strontium in the body may be described by a three-compartment model. Absorption through the gut supplies the first compartment, containing 64 per cent of the absorbed strontium. This freely exchangeable pool includes plasma, extra-cellular fluid and bone surfaces; the effective half-life of the strontium here is 2·7 days. The second compartment contains 18 per cent of the absorbed fraction and represents strontium more closely bound to the apatite crystals of bone, with an effective half-life of 19 days. The third, of the same size as the second, includes strontium attached to the apatite crystal lattice, from which it is released only by resorption of bone. The effective half-life of this portion of the bodily strontium is 750 days.

J. Shimmins (Regional Physics Department) described excretion and retention studies after administration of calcium-45 and strontium-85 over periods of several weeks, at various levels of dietary calcium. The skeletal retention of strontium-85 was less than that of calcium-45 at all levels of dietary calcium intake. Measurements on simultaneous plasma and urine samples showed the urinary excretion of strontium-85 to be more than three times that of calcium-45. It is not clear whether this discrimination arises at the glomerular filtration stage (because of a difference in the extent to which calcium and strontium are bound to plasma proteins) or at the tubular reabsorption stage. Nor is it clear whether the apparent difference in skeletal uptake between calcium and strontium denotes a genuine difference in mineral transfer rates at the bone surface—or is merely a consequence of the undoubted discrimination (favouring excretion of strontium) at the gut and the kidney.

In a review of this work, A. Catsch (Technische Hochschule, Karlsruhe) reported that no convincing successes had been obtained by methods so diverse as isotopic dilution (through addition of stable strontium to the diet), demineralization of bone (for example, by administration of parathyroid hormone or ammonium chloride), blocking of tubular reabsorption in the kidney (by administration of various diuretics) or chelation. Supporting evidence came from Herta Spencer (Veterans Administration Hospital, Hines, Illinois), who described extensive studies on human subjects in a metabolic ward, using calcium-45 and strontium-85 as tracers. When glycerophosphate was added to the diet, raising the daily intake of phosphorus from 600 mg/day to 1,600 mg/day, the absorption of strontium (as inferred from measurement of plasma levels of strontium-85) was reduced. Addition of calcium to the diet gave inconclusive results but administration of stable strontium, even in quite large amounts, appeared to increase the absorption of strontium-85.

Experiments with young animals have suggested that the absorption of both calcium and strontium from the small intestine is enhanced by the presence in the diet of certain carbohydrates (such as lactose) and amino acids (such as lysine); Spencer found no such effect in adult human subjects. Other substances, including oestrogens and corticosteroids, known to influence calcium metabolism in man, were also found to be without effect on the retention of strontium.

Naturally-occurring polyuronic acids are capable of complexing with Sr^{++} ions *in vivo*, so preventing transfer across the intestinal mucosa. Deirdre Waldron-Edward (McGill University) reported that the skeletal retention (in rats) of strontium-89 from a single dose was reduced (in some instances by a factor of five) when sodium alginate was administered with the strontium. Large variations in effectiveness were found among samples of alginate, whether obtained commercially or prepared in the laboratory from different species and varieties of seaweed; of the common seaweeds, *Laminaria digitata* was the most successful in this regard and *Fucus vesiculosis* the least successful.

This work is significant in the study of strontium metabolism, though its practical applications are limited. R. Hesp (U.K.A.E.A., Windscale) found that sodium alginate administered 2 min before a tracer dose of strontium-85 inhibited almost completely the uptake of the radiostrontium in the human subject; a smaller effect was observed if the alginate was given 20 min after the strontium-85. There is at present no method for reducing the body burden of strontium-90 acquired (from fall-out) over a period of time.

An unexpected association between strontium and fluorine was suggested by V. A. Knizhnikov (Institute of the Biophysical Ministry of U.S.S.R., Moscow), who reported that the concentration of radioactive and stable strontium in human teeth was lower in towns where the natural fluorine content of drinking water was relatively high. Animal experiments indicated that reduction in the bodily retention of strontium occurred also when the fluorine content was artificially enhanced. The skeletal uptake of calcium was not affected by the fluorine level in drinking water. Knizhnikov's observations were based on experience in several pairs of towns with differing levels of fluorine (but not of other mineral elements) in drinking water, but no substantial differences in dietary strontium intake, whether stable or radioactive.

J. M. A. LENIHAN

ORIGIN OF THE MICROWAVE RADIO BACKGROUND

By PROF. P. J. E. PEEBLES and PROF R. H. DICKE
Palmer Physical Laboratory, Princeton, New Jersey

RECENTLY, Miss Kaufman stated[1] that the newly discovered microwave radio background[2] at 7·3 cm wavelength may be emission from ionized intergalactic hydrogen, rather than primordial fireball radiation from the big bang[3]. In this new picture the intergalactic hydrogen would have a temperature of about 10^6 °K, and a present density of 2×10^{-30} g/cm³. It is assumed in the calculation that as the universe expanded the hydrogen temperature remained constant, at least as far back in time as we can see at 7·3 cm wave-length. In our opinion this assumption is not tenable; it requires that the intergalactic hydrogen temperature remains constant while the hydrogen has expanded by a factor of 10^{17} in volume. To keep the hydrogen temperature constant as it expands by this enormous factor would require a large amount of energy ($2{\cdot}5\times10^{14}$ ergs/g), and much of this energy must be provided in a period of a few years. The power requirement to keep the gas hot while the universe expands is as great as $2{\cdot}8\times10^5$ ergs/sec g, $1{\cdot}4\times10^5$ times the energy production rate of the Sun. No reasonable energy source would be adequate to prevent an adiabatic cooling of the medium during the rapid expansion of the early universe.

For any set of reasonable assumptions ($\rho\leqslant 2\times10^{-29}$ g/cm³, $T>10{,}000$ °K) there would be negligible microwave emission due to bremsstrahlung radiation (free–free transitions) in intergalactic ionized hydrogen in the present state of the universe. Thus, the question of whether or not the present universe contains any appreciable amount of ionized intergalactic hydrogen[4] is not relevant to the explanation of the microwave radio background. Contrary to Kaufman's arguments[1], we believe that the observed microwave background does not provide any appreciable observational restriction on intergalactic matter in the present universe. On the other hand, if ionized intergalactic hydrogen is present, the hydrogen must have been heated up at some time in the past, the energy source presumably being emission from galaxies, and we know that this heating could not have occurred at an arbitrarily early phase in the expansion of the universe. Otherwise, we could trace the expanding, adiabatically cooling universe back in time, to densities and temperatures so high that the material would have been opaque, and so in thermal equilibrium with radiation.

To estimate the emission from an intergalactic plasma we can use the approximate formula for the opacity due to free-free transitions:

$$\varkappa \sim 2\times10^{-23}\lambda^2N^2\,T^{-3/2} \qquad (1)$$

where C.G.S. units are used, and we have ignored the Gaunt correction. Here N is the number density of the intergalactic protons, T is the temperature of the plasma, and λ is the wave-length of the radiation.

We can neglect synchrotron emission processes in the plasma, because at the assumed temperature of 10^6 °K the electrons are non-relativistic, and so would radiate almost exclusively at the cyclotron frequency. The optical depth in the plasma is the integral of relation (1) along a line of sight, where we have to take account of the cosmological red-shift, so that λ varies directly as the expansion parameter $a(t)$, and $N\propto a^{-3}$. While the results do not depend sensitively on the details of the cosmology used, we have assumed for definiteness a matter-filled space with the present value of the acceleration parameter being $q=\frac{1}{2}$. We then have $a\propto t^{2/3}$ and the optical depth from a time t_0 in the past to the present is:

$$\tau=\int_{t_0}^{t}\varkappa c\,dt\cong 1{\cdot}2\times10^{-23}\,c\,t\,\lambda^2N^2\,T^{-3/2}\,[(1+Z)^{5/2}-1]$$
$$\cong 1{\cdot}1\times10^{-7}\,\lambda^2\,Z^{5/2}\,T^{-3/2} \qquad (2)$$

In this equation t is the present age of the universe, λ and N are evaluated in the present epoch of the universe, and Z is the value of the red-shift $\Delta\lambda/\lambda$ suffered by a photon in the time interval from t_0 to t. In the integration the temperature T is assumed constant. However, the main contribution to this integral occurs near the lower limit (t_0) and the physically significant assumption is that the temperature be constant during these early times. In the second line we have set $N=1{\cdot}2\times10^{-6}$ cm⁻³, following Kaufman[1], we have taken $t=\frac{2}{3}\,H^{-1}=6{\cdot}6\times10^9$ yr, where H is Hubble's constant, and we have assumed $Z\gg1$.

We can see back in time, and into the plasma, to about unit optical depth, that is, back to a red-shift:

$$Z\cong 6\times10^2\,T^{3/5}\,\lambda^{-4/5} \qquad (3)$$

Almost all radiation observed at present would have had its origin during these early times. Consequently, assuming that the hydrogen temperature has been constant, the radiation temperature T_r observed now at wavelength λ is

$$T_r\cong T/Z\cong 1{\cdot}7\times10^{-3}\,T^{2/5}\,\lambda^{4/5} \qquad (4)$$

Adopting a plasma temperature $T=1\times10^6$, we find from equation (4) that at $\lambda=7{\cdot}3$ cm:

$$T_r\cong 2\ ^\circ\mathrm{K} \qquad (4)$$

in agreement with the value $T_r=3{\cdot}7$ °K given by Kaufman[1]. For $\lambda=7{\cdot}3$ cm, equation (3) gives:

$$Z_1\cong 5\times10^5 \qquad (5)$$

In this calculation we have followed Kaufman[1] in ignoring energy transfer from matter to radiation due to scattering by free electrons. For electrons at temperature T the average energy transfer to a low-energy photon in each scattering is about $\delta E/E\cong 4\,kT/mc^2$. At a red-shift $Z=5\times10^5$ (equation (5)) in the past the maximum energy transfer to a low-energy photon in a characteristic expansion time of the universe is:

$$\delta E/E\cong 4\,kT\,\sigma\,Nc\,(\dot a/a)^{-1}/mc^2$$
$$\cong 1{\cdot}8\times10^{-11}\,(Z+1)^{5/2} \qquad (6)$$
$$\cong 3\times10^3$$

In computing the rate of the reactions we have ignored the correction for stimulated emission. Hubble's constant, $\dot a/a$, is assumed to be larger than the present value by

the factor $(Z+1)^{3/2}$. The energy density in radiation does not introduce a significant error here, because the mass density in radiation for a black-body spectrum at 10^6 °K would be only a factor of 10 larger than the assumed total matter density at this epoch. It is seen from equation (6) that energy transfer to the radiation due to free electron scattering is important until the red-shift has decreased to $Z=1\times10^4$. The effect is to move radiation quanta from lower energies to energies approaching kT. However, for the spectrum (4) the available number of low-energy quanta is so small that this could not substantially increase the radiation intensity at higher frequencies. This means that the red-shift required to explain the observed microwave background on the basis of this model could not be substantially less than the value given in equation (5).

According to equation (5), we would be receiving radiation emitted when the mean density in the universe was 10^{17} times larger than it is now. Evidently the present condition of the intergalactic material is of no interest for the radio background. One important question is whether the temperature could have been constant during the epoch in the past when emission from the plasma would have been appreciable.

It is a well-known result of relativistic cosmology that in the absence of internal energy sources a gas uniformly filling the space cools adiabatically with the expansion of the universe. Furthermore, this result does not even require relativity for its demonstration.

To discuss this problem it is convenient to limit our view at this early epoch to a small spherical volume V. We suppose that the hydrogen is expanding with the general expansion of the universe, and that V is expanding at the same rate, so that the mass within V remains constant. Assuming that the radius R of the sphere is much less than cH^{-1}, where $H_{(t)}$ is the value of Hubble's constant, the sphere would be expanding at a rate $\dot{R}=HR$ much less than the velocity of light. Thus, we can discuss the energy content of V in strictly classical, Newtonian terms[5]. In particular, the over-all structure of the universe appears to be isotropic, and this symmetry implies that the matter outside V cannot contribute to the gravitational field within V.

It is assumed that the material within the volume is expanding with the general expansion. The ordinary kinetic pressure resulting from the gas at the surface of V is $2NkT$, so that the material within the system is doing work at the rate:

$$-\dot{U} = p\dot{V} = 2NVkT\dot{V}/V$$

$$= 6NVkT\dot{a}/a \qquad (7)$$

If the temperature within V is to remain constant this work must be supplied by some energy source other than the thermal energy of the material. The only available sources are nuclear burning and the energy release accompanying the localized gravitational collapse of bodies inside V.

It is easy to see that nuclear burning in any known star could not be an appreciable energy source. It is conceivable that the most massive stars achieve 1 per cent conversion of mass to energy in a life-time of 10^6 years. This is a mass to energy conversion ratio of 3×10^{-7} in a characteristic expansion time of the universe ($H^{-1}=30$ yr). However, from equation (7) the energy requirement per unit mass of gas in the characteristic expansion time would be $6\,kT/m_pc^2=5\times10^{-7}$ if the temperature is $T=1\times10^6$ °K. Here m_p is the mass of a proton. Thus, for any reasonable assumption about the amount of material burned in such massive stars, this energy source is inadequate to keep the hydrogen temperature constant.

Energy is also released if material is collapsing to form bound systems. The most efficient established way to obtain energy in this way would be to form massive stars, with central temperature $T_*=3\times10^7$ °K. The temperature limit is set by the requirement that the nuclear energy release be sufficiently slow that the star does not explode. If the mass of such a star is M_*, we know that the energy which is radiated during the formation of the star is given by the formula:

$$U \cong 1{\cdot}6\,kT_*\,M_*/m_p \qquad (8)$$

The numerical factor follows from a polytropic model with polytropic index n in the range 2–3. If the rate of transformation of mass to stars within V is $\dot{M}$, the rate of energy release due to collapse is:

$$\dot{U} = \dot{M}U/M_* \cong 1{\cdot}6\,kT_*\,\dot{M}/m_p \qquad (9)$$

Comparing equations (7) and (9), we obtain the required rate of transformation of mass to bound systems:

$$\dot{M}/M \cong 4\frac{T}{T_*}\frac{\dot{a}}{a} \cong {\cdot}13\,\frac{\dot{a}}{a}, \qquad (10)$$

if $T=1\times10^6$ °K. Note that the result is independent of the mass M^* of the condensation. In order to preserve a constant temperature, stars or other more massive condensations must have been forming at a rate in excess of 10 per cent of the total mass available in hydrogen during each characteristic expansion time of the universe (about 20 years at this epoch). Notice also that the mean density here is 10^{12} times the mean density within a galaxy now, so that the galaxies could not have existed in their present forms. In this model an unreasonably large fraction of all the hydrogen in the universe would have been consumed before the galaxies could have formed.

It is concluded that the energy which would be required to hold the hydrogen temperature constant would not be available on any reasonably satisfactory picture for energy generation in the early universe. Apparently it is preferable to suppose that in the early, highly contracted universe matter and radiation were in thermal equilibrium[3]. When the temperature dropped to 4,000 °K the hydrogen would have recombined, and further expansion would have cooled any uniformly expanding hydrogen below the black-body radiation temperature. There is reason to suppose that the galaxies would have started to form at this epoch[6]. Later energy radiated from the galaxies might have heated up any remaining intergalactic hydrogen, but we have emphasized that this ionized hydrogen could not lead to any appreciable microwave background.

A direct experimental test of the model proposed by Kaufman[1] has been provided by the Princeton microwave experiment at 3·2 cm wave-length which has been performed by our colleagues D. T. Wilkinson and P. G. Roll[7]. According to equation (4) the radiation temperature would vary approximately as $\lambda^{4/5}$, while if the background is the primordial fireball, the temperature is, of course, independent of wave-length. It seems that the Princeton and Bell Laboratories' experiments are compatible with the black-body radiation spectrum but not with the spectrum predicted by equation (4).

This research was supported in part by the National Science Foundation and the Office of Naval Research of the U.S. Navy.

INTERPRETING THE COSMIC MICROWAVE BACKGROUND

By PROF. DAVID LAYZER
Harvard College Observatory, Harvard, Massachusetts

THE observation by Penzias and Wilson[1] of an isotropic microwave background, later confirmed by Roll and Wilkinson[2], has received two conflicting interpretations. Dicke, Peebles, Roll and Wilkinson[3] postulate a universe of the type considered by Gamow[4], in which the energy density of radiation exceeds that of matter near the beginning of the expansion, and interpret the observed radiation field as a remnant of the initial 'flash'. According to the second interpretation, the observed radiation was emitted between 10 and 10^5 years after the beginning of the expansion by ionized hydrogen at a nearly constant temperature in the range 10^4–10^6 °K. Miss Kaufman[6] has shown that this model[5] is consistent with the observations of Penzias and Wilson and of Roll and Wilkinson as well as with measurement of the radio-noise background between 10 and 400 Mc/s. At millimetre wave-lengths, where no measurements have as yet been made, the constant-temperature model predicts a much lower value of the background temperature than the model of Dicke and Peebles. The total energy density of radiation is also several orders of magnitude smaller in the constant-temperature model than in the model of Dicke and Peebles[7].

In the preceding article, Dicke and Peebles criticize the constant-temperature model, which they consider to be inconsistent with the cosmological energy equation:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\varepsilon S^3) + p\frac{\mathrm{d}S^3}{\mathrm{d}t} = 0 \qquad (1)$$

Here S is the cosmic scale factor, ε is the internal-energy density, and p is the cosmic pressure. In a perfect gas of uniform density ε and p are both positive and are related by the usual equation of state. This is the situation envisaged by Dicke and Peebles. The constant-temperature model, however, describes a universe in which, owing to local non-uniformities in the distribution of matter, the internal energy is negative and the pressure is nearly zero. Thus the internal energy of a co-expanding volume element remains approximately constant in time.

Let us consider a statistically homogeneous and isotropic, but non-uniform, distribution of matter. The fluctuating part of the density field gives rise to short-range gravitational forces analogous to the screened Coulomb forces in a macroscopically neutral plasma. These forces are derived from a potential φ related to the fluctuating component of the density, $\tilde{\rho} \equiv \rho - [\rho]$, through Poisson's equation $\nabla^2\varphi = 4\pi G\tilde{\rho}$. (Brackets [ ] are herein used to denote ensemble averages. The ergodic theorem of Birkhoff and Khinchin ensures that these coincide with spatial averages if the scale of the local irregularities is finite.)

If the particle velocities are non-relativistic, the internal-energy density and the cosmic pressure may each be written as the sum of a kinetic, a gravitational, and a radiative contribution[8,9]:

$$\varepsilon = \varepsilon_k + \varepsilon_g + \varepsilon_r, \quad p = p_k + p_g + p_r \qquad (2)$$

where

$$\varepsilon_k = \tfrac{2}{3}p_k = \tfrac{1}{2}[\rho v^2], \quad \varepsilon_g = p_g = \tfrac{1}{2}[\rho\varphi], \quad \varepsilon_r = 3p_r \qquad (3)$$

Here v denotes the velocity of a particle relative to its instantaneous locally inertial frame of reference. It is given explicitly by the formula:

$$v = S(t)\frac{\mathrm{d}\bar{x}}{\mathrm{d}t} \qquad (4)$$

where the components of $\bar{x}$ are 'co-moving' spatial co-ordinates. Energy exchange between the radiation field and the matter is described by the equation:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\varepsilon_r S^3) + p_r\frac{\mathrm{d}S^3}{\mathrm{d}t} = (q-r)S^3 \qquad (5)$$

where q and r represent, respectively, the mean rates of emission and absorption of radiant energy per unit volume. On inserting equations (2) and (5) in (1), we obtain:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\varepsilon' S^3) + p'\frac{\mathrm{d}S^3}{\mathrm{d}t} = (-q+r)S^3 \qquad (6)$$

where

$$\varepsilon' = \varepsilon_k + \varepsilon_g, \quad p' = p_k + p_g \qquad (7)$$

Radiative processes always act to diminish the quantity $\varepsilon' S^3$, because in an expanding universe photons lose energy in flight. (The right-hand side of equation (6) may, however, assume positive as well as negative values. That is, the mechanical part of the internal energy of a co-expanding volume element may decrease less rapidly with the expansion than it would in the absence of radiation.)

The gravitational contribution to the internal-energy density may be expressed in the form[9,10]

$$\varepsilon_g = -2\pi G[\rho]\alpha^2\lambda^2 \qquad (8)$$

where

$$[\tilde{\rho}^2] \equiv \alpha^2[\rho]^2, \quad \int_0^\infty [\tilde{\rho}(\mathbf{x}+\mathbf{r})\,\tilde{\rho}(\mathbf{x})]\,r\mathrm{d}r = \lambda^2[\tilde{\rho}^2] \qquad (9)$$

The quantities α and λ measure, respectively, the amplitude and the scale of the local density fluctuations. From equation (8) and the relation $p_g = \varepsilon_g$ it follows that the gravitational contribution to the cosmic pressure is always negative. Thus, we cannot immediately conclude that the internal energy of a co-expanding volume element must decrease in the absence of energy sources. The cosmic expansion tends to decrease the kinetic contribution to the internal energy and to increase the (negative) gravitational contribution. The sum of the two contributions may increase, decrease, or remain constant.

Observational evidence strongly suggests that at the present time the part of the internal-energy density of the universe associated with structure of galactic and supergalactic scale is negative. (The part of the internal energy associated with stellar structure is not relevant to the present discussion.) The actual value of this part of $\varepsilon'/[\rho]$ is difficult to estimate because we have no reliable information about the density or temperature of intergalactic matter, but it may perhaps lie in the range -10^{12} to -10^{14} ergs/g. The corresponding range of kinetic temperatures is:

$$10^4 \lesssim T_k \lesssim 10^6 \text{ °K} \qquad (10)$$

It has been shown elsewhere[9,11] that $p' \simeq 0$ provided that (i) $\varepsilon' < 0$, and (ii) $\tau \ll t$, where τ is a relaxation time associated with the density fluctuations. Under these conditions equation (6) reduces to:

$$\frac{\mathrm{d}}{\mathrm{d}t}(\varepsilon' S^3) = (-q+r)S^3 < 0 \qquad (11)$$

Thus the non-radiative part of the internal energy of a co-expanding volume element diminishes monotonically with time. It follows that the quantity $\varepsilon_k/[\rho]$, which is proportional to the kinetic temperature of the distribution, increases monotonically with time, and that the amplitude α of the density fluctuations increases at least as fast as $S^{1/2}$. However, the temperature of the gas cannot have been appreciably smaller than 10^4 °K at any time during the period when $p' \simeq 0$, for at significantly lower temperatures the gas would have been so little ionized that radiative energy losses would have been negligible. The kinetic temperature would then have remained constant, and its present value would have been less than the lower limit given by equation (10). Considerations of the rate of energy loss by radiation suggest that the kinetic temperature of the gas would in fact have remained near 10^4 °K until galaxies began to separate out.

The preceding remarks may serve to indicate how certain properties of the present-day cosmic distribution of matter can be related to the kinetic temperature of the pre-galactic distribution. A deductive cosmogonical theory should relate this temperature in turn to the initial conditions of the universe. This problem has been briefly discussed elsewhere[11] and will be treated more fully in a forthcoming paper. The main point of the discussion is that the initial thermodynamic temperature of the universe must be assumed to be very low if the internal energy is ever to become negative. The simplest assumption is that the initial state of the universe is one of thermodynamic equilibrium at zero temperature. Such a universe would be matter-dominated throughout and would not possess a 'fossil' radiation field of the kind postulated by Dicke and Peebles.

The objections raised by Dicke and Peebles to the constant-temperature model seem to be based in part on their classical interpretation of equation (1). This interpretation encounters certain well-known conceptual difficulties. For example, the equation (but not the physical argument used to derive it) applies to a wholly collisionless gas. Again, the symmetry of the cosmic distribution would seem to ensure that one part of it cannot do work on another. It may perhaps be more satisfactory to interpret equation (1) as expressing non-conservation of energy resulting from the use of a non-inertial co-ordinate system. The quantities ε and p are defined in terms of particle velocities and momenta calculated with respect to the instantaneous locally inertial frames of reference of the individual particles (see equation (4)). With the help of Einstein's formula for the composition of velocities in special relativity, it can easily be shown[12] that the momentum of a test particle moving in a uniform and isotropic universe varies like S^{-1}. From this purely kinematic result it is possible to deduce the cosmological energy equation (1) for a uniform, isotropic, and collisionless distribution of gravitating particles, as well as the classical formula $\nu \propto S^{-1}$ for the frequency of a photon in a uniform and isotropic universe. The additional effects described by the cosmological energy equation when density fluctuations are present also admit a purely kinematic interpretation of an obvious kind.

TANIFUJI–BUTLER MODEL FOR DEUTERON STRIPPING REACTIONS

By DR. C. A. PEARSON

Australian Atomic Energy Commission, Lucas Heights, Australia, and The Neils Bohr Institute, Copenhagen, Denmark

AND

DR. J. M. BANG

The Neils Bohr Institute, Copenhagen, Denmark

A MODEL which has been referred to as the 'snapshot' or 'sudden approximation' model has been recently proposed by Tanifuji[1] and Butler[2] for analysing (d,p) stripping reactions.

These authors emphasize that the deuteron is a large and weakly bound system. Such a system should stretch and dissociate as it encounters the surface of the target nucleus. To the extent that it does not properly take account of such stretching and dissociation, the conventional distorted wave Born approximation provides an unsatisfactory description of (d,p) stripping reactions.

The idea that the weak binding of the deuteron should be emphasized is not new. It was basic to the original Butler model[3]. The new feature in the 'snapshot' model is the use of the 'sudden approximation' to take account of this weak binding.

Although it may be desirable to develop a model of (d,p) stripping reactions which retains the emphasis of the original Butler model, we must point out that the use of the 'sudden approximation' is not justified.

We shall show in this article that the 'sudden approximation' cannot be used for the (d,p) stripping reaction, since it contains no mechanism by which the neutron can propagate into the bound final state. The exact 'sudden approximation' amplitude is zero. The non-zero amplitude of the 'snapshot model' results from a further 'approximation'. This further 'approximation' is artificial, and the stripping mechanism which results from it is unphysical.

Let us consider a (d,p) stripping reaction in the barycentric frame. We make the usual assumption that the residual nucleus contains a neutron bound to the unexcited target nucleus 'core'. We denote by H the total Hamiltonian, E the total energy of the system, and H_A the target Hamiltonian. We represent by V_n, V_p and V_{np} the neutron-target, proton-target, and neutron-proton interactions, respectively.

The exact amplitude for the (d,p) stripping reaction can be written[4]:

$$T_{fi} = \langle \psi_f \mid V_{np} \mid \Psi^{(+)} \rangle \qquad (1)$$

where $\Psi^{(+)}$ is the total wave function satisfying:

$$(H-E)\Psi^{(+)}=0 \tag{2}$$

The final state wave function $\psi_f^{(-)}$ which describes a proton scattered from the target nucleus 'core' satisfies:

$$\psi_f^{(-)}=0_f+\frac{1}{E-K_m-K_p-V_n-H_A-i\varepsilon}\,V_p\psi_f^{(-)} \tag{3}$$

where

$$0_f=\exp\,(i\,k_p'\cdot r_p)\,B(r_n,\xi) \tag{4}$$

where kp' is the momentum of the outgoing proton, and $B(r_n, \xi)$ the wave function of the residual nucleus. From equation (3), we see that the wave function $\psi^{(-)}$ is an eigenfunction of the Hamiltonian:

$$H_f=K_n+K_p+H_A+V_n+V_p \tag{5}$$

To obtain the 'sudden approximation' to the total wave function $\Psi^{(+)}$ we neglect the effects of the deuteron binding force once the deuteron interacts with the target nucleus. The 'sudden approximation' wave function $\Psi_d^{(+)}$ is then given by:

$$\Psi_d^{(+)}=\int dk_p G(k_p,k_d)\varphi_{np}^{(+)}(k_n,k_p,r_n,r_p,\xi) \tag{6}$$

where $\varphi_{np}^{(+)}$ satisfies:

$$\varphi_{np}^{(+)}=\left[1+\frac{1}{E_{np}-H_f-i\varepsilon}\,(V_n+V_p)\right]A_0(\xi)e^{ik_p\cdot r_p}e^{ik_n\cdot r_n} \tag{7}$$

with

$$E_{np}=\frac{\hbar^2}{2m}\,(k_p^2+k_m^2) \tag{8}$$

and we have chosen the energy of the ground state $A_0(\xi)$ of the target nucleus to be zero.

The wave function $\varphi_{np}^{(+)}$ in the expression (7) satisfies:

$$(H_f-E_{np})\varphi_{np}^{(+)}=0 \tag{9}$$

It describes two free nucleons scattering from the target nucleus. The 'sudden approximation' (6) for the total wave function contains only scattering states of the Hamiltonian H_f, and no states in which the neutron is bound to the target nucleus. It is therefore orthogonal to the final state $\psi_f^{(-)}$.

We follow the method of Butler[2] and write the exact amplitude (1):

$$T_{fi}=<\psi_f^{(-)}\mid E-H_f\mid\Psi^{(+)}> \tag{10}$$

We then replace $\Psi^{(+)}$ with the wave function (6) to obtain:

$$T_{fi}=\int dk_p G(k_p,k_d)<\psi_f^{(-)}\mid E-E_{np}\mid\varphi_{np}^{(+)}> \tag{11}$$

Because $\psi_f^{(-)}$, $\varphi_{np}^{(+)}$ are eigenfunctions of the same Hamiltonian, H_f corresponding to the different energies E, E_{np} respectively, the amplitude (11) is zero.

The 'snapshot' amplitude can be obtained from the amplitude (11) by introducing 'approximate' optical model wave functions. We replace $\psi_f^{(-)}$ with the wave function:

$$\psi_f{}^{A(-)}(r_n,r_p,\xi)=\chi_p^{(-)}(r_n,k_p')U(r_n)A_0(\xi) \tag{12}$$

where $A_0(\xi)$ is the ground state of the target nucleus, $U(r_n)$ the bound state of the captured neutron, and $\chi_p^{(-)}(r_p,k_p')$ an optical model distorted wave function which corresponds to the free proton momentum k_p. The wave function (12) satisfies:

$$[H_A+K_n+K_p+\mathcal{U}_n+\mathcal{V}_p]\psi_f{}^{A(-)}=E\psi_f{}^{A(-)} \tag{13}$$

where $\mathcal{U}_n$ is a real shell model neutron potential, $\mathcal{V}_p$ a complex optical model potential for the proton. We replace $\varphi_{np}^{(+)}$ with the wave function:

$$\varphi_{np}{}^{A(+)}=\chi_p^{(+)}(k_p,r_p)\chi_n^{(+)}(k_n,r_n)A_0(\xi) \tag{14}$$

where $\chi_p^{(+)}$, and $\chi_n^{(+)}$ represent optical model proton and neutron distorted wave functions. The wave function (14) satisfies:

$$[H_A+K_n+K_p+\mathcal{U}_n+\mathcal{V}_p]\varphi_{np}{}^{A(+)}=E_{np}\varphi_{np}{}^{A(+)} \tag{15}$$

where $\mathcal{V}_n$ is a complex optical model potential for the neutron.

The 'snapshot' model amplitude is then

$$T_{fi}{}^{S}=\int dk_p G(k_p,k_d)<\chi_p^{(-)}\mid\chi_p^{(-)}> \\ <U(r_n)\mid E-E_{np}\mid X_n^{(+)}(k_n,r_n)> \tag{16}$$

This amplitude is not zero because the Hamiltonians which appear on the left of equations (13) and (15) are no longer identical, so that the wave functions $U(r_n)$, $\chi_n^{(+)}(k_n,r_n)$ are not orthogonal.

If the 'snapshot' model has any validity, there must be some physical grounds for preferring the 'approximate' elastic scattering wave functions $\psi_f{}^{A(-)}, \varphi_{np}{}^{A(+)}$ to the 'exact' many-particle wave functions $\psi_f^{(-)}, \varphi_{np}^{(+)}$ in the 'sudden approximation' amplitude. These grounds have not been mentioned in the literature, although they must form the whole basis of the 'snapshot' model.

To discuss the physical content of the 'snapshot' amplitude we first consider a simple model reaction in which a deuteron impinges on a real nucleon potential. Intentively, we imagine that this model reaction contains the essential features of the real reaction. For this model reaction we see:

$$\psi_f^{(-)}=\psi_f{}^{A(-)}$$

$$\varphi_{np}^{(+)}=\varphi_{np}{}^{A(+)}$$

so that the amplitudes (16) and (11) are identical. The 'snapshot' result implies that the neutron is never captured when the deuteron is stripped.

Therefore we believe that the 'snapshot' model does not represent the physical stripping mechanism. The essential physical features have been lost in making the 'sudden approximation' which leads to the vanishing amplitude (11).

The main difficulties of the 'snapshot' model are illustrated in the neutron capture amplitude:

$$<U(r_n)\mid E-E_{np}\mid\chi_n^{(+)}(r_n,k_n)> \tag{17}$$

In order to be non-zero, this amplitude does not conserve energy. Thus, the mechanism for the neutron capture is somewhat artificial.

We have seen that the 'sudden approximation' replaces the total wave function with a packet of free neutron–proton pairs. In each pair the neutron and proton scatter from the target nucleus but do not interact with each other. Strictly the neutron cannot transfer energy to the proton and thus cannot lodge in a bound state without exciting the target nucleus 'core'.

The introduction of the optical model wave function in the capture amplitude (17) provides an artificial means for the incident neutron to shed its energy. We thus conclude that the 'snapshot' model does not represent the proper nature of the physical stripping mechanism. It has been shown elsewhere[5] that its predictions are in poor agreement with experiment.

SOME ENGINEERING ASPECTS OF NON-NEWTONIAN FLOW

By DR. J. HARRIS
Department of Mechanical Engineering, Queen's College, Dundee

THE subject of non-Newtonian flow is of acknowledged complexity. Treatment of it in engineering and other fields is frequently of an empirical nature representing a convenient means of correlating experimental data, probably for design and scaling procedures. Such treatment may not be of permanent value and subject to replacement by alternatives as the physical phenomena become better understood and further experimental data become available.

The following comments on (1) the measurement of normal stress in laminar viscoelastic flow, (2) dynamic similarity in non-Newtonian flow through a pipe, and (3) turbulent velocity profiles, are presented in the hope that they will assist in clarifying some of the confusing points to be found in the literature at the present time.

(1) Pitot Tube in Viscoelastic Flow

The simple theory treating the pitot tube technique for measuring velocity profiles is based on the Bernoulli equation, for incompressible flow:

$$\frac{p_1}{\rho} + \frac{u_1^2}{2} = \frac{p_2}{\rho} + \frac{u_2^2}{2} + E_L \qquad (1)$$

which is essentially a statement of the conservation of energy for a unit mass of material flowing from a point upstream of the pitot tube entrance in the undisturbed region (denoted by suffix 1) to the stagnation point at the tube entry (denoted by suffix 2). In equation (1) p is the fluid pressure, ρ is the (constant) density, u is the velocity and E_L is the energy transformed into heat between 1 and 2.

Neglecting the term E_L and noting that the velocity at the stagnation point is zero the well-known expression for the upstream velocity is obtained:

$$u_1 = \sqrt{\frac{2\,(p_2 - p_1)}{\rho}} \qquad (2)$$

It is satisfactory to neglect the E_L term at the axis of flow in laminar flow through a duct or more generally where the pathline to the stagnation point is a line connecting points of zero deformation rate. There is an error in using equation (2) for other pathlines, but a discussion of this would be out of context here.

Recently there has been a proposal that a pitot tube, used in the same way as for velocity profile measurement, is capable of measuring the axial stress known to be generated in laminar viscoelastic flow through a duct[7]. In contrast to the treatment for velocity profile measurement which is based on the conservation of energy, here the treatment is based on the conservation of momentum.

A suitable form for the steady state expression of conservation of linear momentum is, for an arbitrary fix surface in the flow (sometimes termed the control surface),

$$\int_A T^i \mathrm{d}\sigma = \tfrac{1}{2}\rho \int_A u^i u^j \nu_j \mathrm{d}\sigma \qquad (3)$$

where T^i is the surface force tensor per unit area, u^i (u^j) is the velocity vector, and ν_j is the unit normal vector at the surface area element $\mathrm{d}\sigma$. The density is assumed constant and the integrals are taken over the complete surface. The surface force tensor is related to the stress tensor by:

$$T^i = \tau^{ij}\,\nu_j \qquad (4)$$

Suppose a cylindrical control surface is chosen now which is the same radius as the 'impact' opening of the pitot tube (r') and extends upstream a distance z' into the region of flow where disturbances due to the introduction of the pitot tube are just undetectable. In the cylindrical co-ordinate system (r, θ, z) the velocity components at a point are (v, w, u). Assuming that with small error the w component of velocity may be neglected, then (3) may be rewritten as:

$$\int_0^{r'} \widehat{zz}_1(r) r\mathrm{d}r - \int_0^{r'} \widehat{zz}_2(r) r\mathrm{d}r + r' \int_0^{z'} \widehat{zr}(r',z)\mathrm{d}z = \tfrac{1}{2}\rho\left(r' \int_0^{z'} u(r',z)v(r',z)\,\mathrm{d}z - \int_0^{r'} u_1^2(r) r\mathrm{d}r\right) \qquad (5)$$

The quantity measured by the manometer attached to the impact opening is:

$$\int_0^{z'} \widehat{zz}_2(r) r\mathrm{d}r = \tfrac{1}{2}\,(r')^2\,\breve{\rho d}\; g(\Delta h) \qquad (6)$$

where $\breve{\rho d}$ is the density difference of the two fluids in the manometer limbs and Δh is the difference in fluid levels.

By putting $p_1 = \widehat{zz}_1$, $p_2 = \widehat{zz}_2$, neglecting the integrals $r' \int_0^{z'} \widehat{zr}\mathrm{d}z$, $\int_0^{z'} uv\mathrm{d}z$ (or assuming their equivalence) and assuming no variation of any of the quantities $\widehat{zz}_1$, $\widehat{zz}_2$ and u with r the equation (2) may be retrieved from (5). It has previously been mentioned that the energy approach to the derivation of (2) involves the neglect of viscous dissipation of energy so for consistency the neglect of $\int_0^{z'} uv\mathrm{d}z$ is implied in (5).

If the flow is viscoelastic and the integrals $\int_0^{z'} \widehat{zr}\mathrm{d}z$, $\int_0^{z'} uv\mathrm{d}z$ are similarly neglected, then there arises the possibility of sensing the upstream stress in the direction of flow by using (5) if u is known, as was discussed by Savins[9]. However, while the neglect of the shear stress $\widehat{zr}$ may be acceptable in the rapid flow of substances of small viscosity because:

$$r' \int_0^{z'} \widehat{zr}\mathrm{d}z \ll \rho \int_0^{r'} u_1^2 r\mathrm{d}r \qquad (7)$$

it is likely that the flow rate would have to be exceedingly rapid for the same assumption in the case of viscoelastic materials because they are often quite viscous.

As is the case for inelastic flow it is possible to consider the application of the conservation of energy to a particle moving from a point upstream to the stagnation point in front of the pitot tube opening, assuming that at this point it relaxes completely, then:

$$Ep_1 + E_{E1} + \tfrac{1}{2}\rho u_1^2 = \frac{p_2}{\rho} + E_L \qquad (8)$$

Here Ep_1 and E_{E1} are the pressure and elastic energy per unit mass respectively at a point upstream of the pitot opening. The other symbols are as previously defined for equation (1). There are considerable difficulties in using equation (8) to measure normal stress; not only would E_L in general be finite but the expression for Ep_1+E_{E1} as a function of $\widehat{zz}_1$ is unknown. From Savins[9] treatment:

$$\widehat{zz}_1 = Ep_1 + E_{E1} \qquad (9)$$

which may be true in isolated cases, but of course is not an acceptable general hypothesis.

There are other reasons why a pitot tube would be unsatisfactory for normal stress measurement such as the bending of the streamlines around the pitot tube entrance which could introduce aberrations into the stress measurement there[6].

In conclusion it may be stated therefore that the pitot tube is less likely to be as useful as other available methods for sensing the stress in the direction of flow[7].

(2) Dynamic Similarity

In Newtonian flow the familiar Reynolds number has proved an invaluable means for correlating experimental data and it is natural to search for a corresponding expression for non-Newtonian flow; however, it may be stated that although numerous attempts have been made, no generally acceptable similarity group has yet emerged. It may be expected that no single dynamic similarity group will be entirely adequate for non-Newtonian fluids since in turbulent flow the fluid elements are subjected to unsteady motion and it is doubtful whether any non-Newtonian fluid is purely viscous in its response to this type of motion. It is known for example that even suspensions of hard particles may show both in-phase and quadrature components of stress (and higher harmonics) in oscillatory experiments[8], which may arise not only from elastic effects but also from the effects of finite diffusion coefficients. None of the rheological formulae such as the 'power-law'*:

$$\tau = K\dot{\gamma}^n \qquad (10)$$

where τ is the shear stress, K is a constant coefficient, $\dot{\gamma}$ is the shear rate and n is a constant index, or the Bingham equation:

$$\tau - \tau_y = \mu_p\dot{\gamma} \qquad (11)$$

where τ_y is the yield stress, μ_p is the plastic viscosity, or the Casson equation:

$$\tau^{\frac{1}{2}} - \tau_y^{\frac{1}{2}} = c^{\frac{1}{2}} \qquad (12)$$

where c is a constant (to list only a few of those proposed), is satisfactory for unsteady motion and could scarcely serve as a basis for tubulent flow studies.

In Newtonian flow the Reynolds number for flow through a tube, diameter D, at a mean velocity of u_m is:

$$N_R = \frac{\rho u_m D}{\mu} \qquad (13)$$

or

$$N_R = \frac{\rho u_m D\,(8u_m/D)}{\tau_{\widetilde{WL}}} \qquad (14)$$

where $\tau_{\widetilde{WL}}$ is the wall shear stress if the flow was laminar (even though the flow may in fact be turbulent). It may be noted that the friction factor:

$$C_f \equiv \frac{\tau_w}{\frac{1}{2}\rho u_m^2} = \frac{16}{N_R} \qquad (15)$$

is automatically obtained from equation (14) in the laminar régime and a graph of log C_f against log N_R is a plot of log x against log $\frac{1}{x}$ which is bound to have a slope of -1. Thus there is no new information to be gained, as has previously been pointed out[2], and experimental data here cannot be taken as demonstrating the utility of a particular dynamic similarity group.

If a steady laminar shearing motion the experimental data can be fitted by equation (10) then for flow through a tube:

$$\tau_{WL} = K'\frac{(8u_m)^n}{D} \qquad (16)$$

where

$$K' = K\frac{(3n+1)^n}{4n} \qquad (17)$$

and by substituting equation (16) into equation (14) the Reynolds number is:

$$N_R = \frac{\rho u_m^{2-n} D^n}{8^n K'} \qquad (18)$$

as derived by Dodge and Metzner[3–5].

Now equation (10) cannot be expected to apply under the conditions prevailing in turbulent flow and thus the similarity group (18) may, at the most, apply only in steady laminar shearing motion.

If the experimental data cannot be fitted by equation (10) even in steady laminar motion it has been proposed to replace K' and n in equation (16) by their point values at the value of $8u_m/D$ (or $\tau_{\widetilde{WL}}$) under consideration. In other words, the tangent to the log $\tau_{\widetilde{WL}}$ against log $(8u_m/D)$ curve at a certain point is the curve of the equivalent 'power-law' fluid which would have the same Reynolds number (equation (18)), that is it would have dynamic similarity. But a dynamic similarity group based on a 'power-law' is of dubious value in turbulent flow and it is not surprising that other authors[2,3] have pointed out the failure of equation (18) to correlate experimental data.

For design and scaling procedures, it is satisfactory to have the relevant correlation of data for a particular fluid; it appears from the work of Bowen[2] that this is possible for a number of different types of non-Newtonian fluids and although a universal friction factor—Reynolds number curve is not achieved this is no serious disadvantage. The empirical correlating equation is:

$$D^x\,\tau_W = L u_m^y \qquad (19)$$

where x, y and L are constants.

(3) Turbulent Velocity Profile

Some time ago, by a dimensional analysis and by matching the velocity profile in the zone near to the pipe wall (where both viscosity and turbulent fluctuations are important with that in the fully turbulent core where viscosity is of minor importance), Millikan produced in an elegant manner the well-known logarithmic form for the Newtonian turbulent velocity profile.

An identical approach was used by Dodge[3] to formulate the logarithmic form for the non-Newtonian turbulent velocity profile utilizing the 'power-law' (equation (10)) which yields:

$$u^+ = A(n)\ln y^+ + B(n) \qquad (20)$$

where u^+ is the dimensionless (time-average) velocity, y^+ is the dimensionless distance from the boundary, A and B are constants for a given value of n. The profile (20) has since been published again[1] with a small correction factor which is a function of N_R.

It is now obvious that both the original and corrected forms are based on an unacceptable hypothesis (10) for turbulent flow.

It is possible, however, to derive an expression for the turbulent velocity profile based on Bowen's empirical

* There are also difficulties in the invariant form $P^{ij} = 2c(e^{ij}\,e_{ij})^{(n-1)/2}\,e^{ij}$, ($e_{ij}$($e^{ij}$) are the covariant (contravariant) components of the strain rate and P^{ij} is the (extra) stress tensor which has been proposed (ref. 10) In oscillatory motion the viscosity can also here become infinitely large and there will be both odd and even harmonics in the stress wave.

correlation and a diameter independence hypothesis such as is used in Newtonian flow to find the 1/7 power law velocity profile. It is hoped to publish this derivation in due course.

CRYSTALLOGRAPHIC SHEAR AND DIFFUSION PATHS IN CERTAIN HIGHER OXIDES OF NIOBIUM, TUNGSTEN, MOLYBDENUM AND TITANIUM

By Dr. STEN ANDERSSON* and Dr. A. D. WADSLEY

C.S.I.R.O. Division of Mineral Chemistry, Melbourne, Australia

It is well known that the ease with which solids interact largely depends on the ready availability of suitable diffusion paths for the ions, and it is our purpose to show that the part played by a specific kind of defect, the crystallographic 'shear plane'[1], may be of vital significance. The existence of closely spaced families of phases is now well established in most transition metal solid-state systems. Niobium oxides of this kind are formed by substituting Ti^{4+}, Nb^{4+} or W^{6+} for Nb^{5+} (refs. 2 and 3), or alternatively by replacing O^{2-} with F^- in high-temperature niobium pentoxide[4]. Similar families of partly reduced tungsten or mixed tungsten–molybdenum oxides[5], and of reduced titanium oxides[6] represented as 'homologous series' with formulae W_nO_{3n-2}, $(Mo,W)_nO_{3n-1}$, and Ti_nO_{2n-1}, respectively, are also readily synthesized. Although the structural inter-relationships within each family have been investigated by crystallographic methods it is becoming increasingly important to understand the physico-chemical principles by which these groups of phases form. We therefore propose a model for a simple diffusion process involving the formation and the subsequent migration of a series of parallel shear planes within a crystal, which can occur rapidly and without drastic local changes of structure.

A shear is defined as a regular defect arising from the compression of a simple structure along certain planes, where the co-ordination polyhedra condense in a different way[1]. Fig. 1*a* represents the structure of NbO_2F (ReO_3-type), and any one octahedron has corners common to the six adjacent octahedra. Nb_3O_7F (Fig. 1*b* and *c*) is related to it, but contains parallel shear planes with every third octahedron in a particular row sharing edges with each of the two nearest octahedra and corners with the next five[7]. Nb_3O_7F, therefore, contains blocks similar to NbO_2F extending infinitely through the crystal in two dimensions, but with a finite width of three octahedra. The niobium, tungsten or titanium families of oxides each contain characteristic shear planes, and the members of one family differ only in the size of the block of the simple parent structure they contain. Their presence diminishes the oxygen-to-metal ratio of the parent phase.

NbO_2F rapidly decomposes at 750° C (ref. 8) according to the equation:

$$4NbO_2F \rightarrow Nb_3O_7F + NbOF_3\uparrow$$

The loss of the volatile phase $NbOF_3$ at the crystal boundaries is followed by the transport of equal numbers of Nb^{5+} and O^{2-} or F^- ions to empty spaces within the crystal. Migrating metal or non-metal ions move into the nearest interstitial position through a barrier of anions which, with their large amplitudes of thermal oscillation, need scarcely be pushed aside from their mean positions. In Fig. 1*b* and *c*, the arrows show the movement of the ions, proceeding by way of the longest O–O distance (3·07 Å) and thereby meeting least resistance.

Any one empty square in Figs. 1*a* and 2*a* bounded by four octahedra represents the projected view of a row in interstitial positions: the atoms migrating from the surface change it into a row of octahedra. In Fig. 2*a* and *b* is illustrated the second postulate of our model, the co-operative transformation in the same way of adjacent rows of empty sites by the movement of the Nb and O atoms in the octahedra labelled 1, 2, 3 and 4. The migration now continues as in Fig. 2*b* and *c* with the atoms 5, 6, 7 and 8, and then in Fig. 2*c* and *d* with 9, 10, 11 and 12. The atoms advance into the next row of interstitial positions of NbO_2F and leave this same structure behind, the net effect being the movement of a shear plane unidimensionally throughout the crystal. More planes form in the same way, and when the reaction is completed, they are frozen into the regular equilibrium positions of the phase Nb_3O_7F (Fig. 1*b* and *c*).

This mechanism is less disruptive than the proposal by Gadó[9] for the closely related WO_3–$W_{20}O_{58}$ reversible transformation. He postulated the extensive formation of vacant anion positions, but his detailed analysis of the diffraction data applies equally well to our model. The shear planes of $W_{20}O_{58}$ are also composed of octahedra sharing edges and corners, but differ from those in Nb_3O_7 by adopting another crystallographic orientation (Fig. 3*a* and *b*). These also move in unison through the crystal, the metals (plus oxygen) marked 2, 4, 6 and 8 in one direction, while the atoms 9 move the other way, and the whole structure takes up a regular periodicity at the conclusion of the reaction. There is no known tungsten oxide W_3O_8 the exact counterpart of Nb_3O_7F and the detailed structure of $W_{20}O_{58}$, which is formed instead, evidently reflects the loss of oxygen atoms alone, from the edges of the crystal. The oxidation of $W_{20}O_{58}$ to WO_3 could be initiated by the migration of the shear planes to the surfaces, where oxygen from the environment is captured, and the octahedral co-ordination for tungsten completed. The closely related members of the homologous series of compounds $(Mo,W)_nO_{3n-1}$ (ref. 5) may result from the loss of some of the more volatile molybdenum as oxide, the particular member of the series which forms thereby depending on the percentage of tungsten it contains.

The proposed diffusion mechanism is not confined solely to substances with the ReO_3 arrangement of atoms—these are comparatively rare in oxide systems. Compounds more commonly contain fragments of this particular structure present only as blocks of limited size, and the family of phases centred around Nb_2O_5 affords

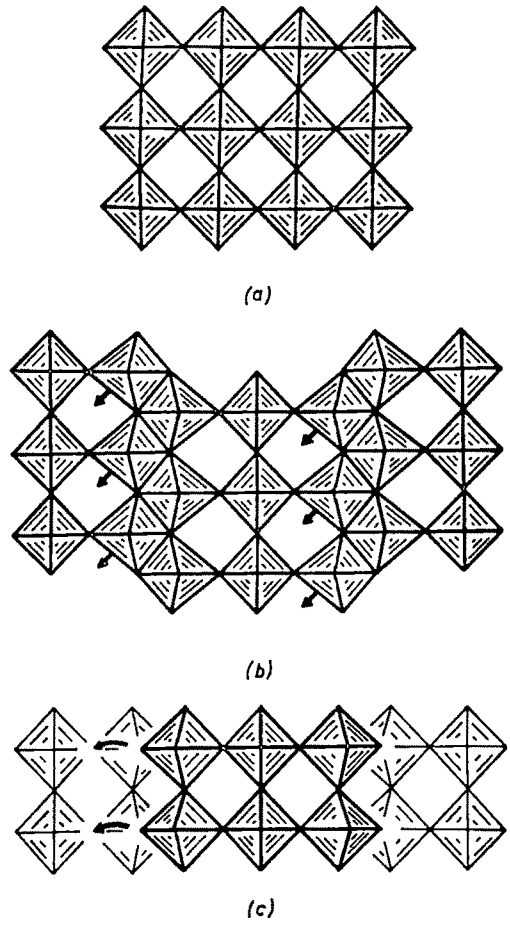

Fig. 1. *a*, Structure of NbO_2F in projection. Each hatched square represents an octahedron, with a niobium and an oxygen atom at the centre, and oxygens (or fluorine) at the corners. *b* and *c*, Two projected views of Nb_2O_5F (non-idealized) showing the relationship to NbO_2F. The shear planes are denoted by the octahedra sharing edges. The migrating niobium and oxygen (or fluorine) atoms move from the octahedra in the directions of the arrows to the interstitial positions (empty squares), which are consequently transformed into octahedra

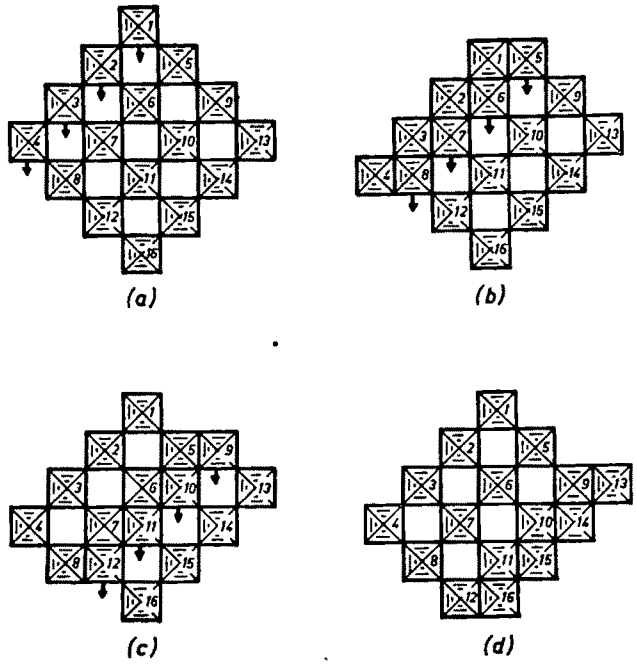

Fig. 2. *a–d*, The formation of a shear plane in NbO_2F and its subsequent migration. Note the resemblance to zone refinement of impure crystals

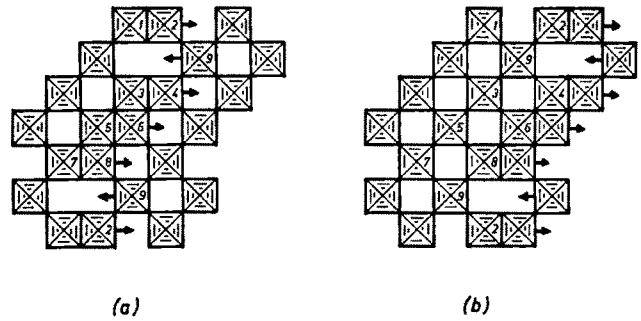

Fig. 3. *a* and *b*, The movement of shear planes in $W_{20}O_{58}$, formed by the reduction of WO_3

many examples of this type. Each oxide containing Nb^{5+} with a substituent metal of higher or lower valency, or with F^- replacing O^{2-}, is distinguished from the others in organization as well as in the size of the blocks[2,3]. Each is the ReO_3 structure containing two parallel but criss-crossing sets of shear planes forming the boundaries of the blocks, and tetrahedrally co-ordinated atoms are often present at their intersections. The tetrahedral atoms do not represent impenetrable barriers to the diffusion of metal or oxygen, as they can move unrestrained to any of four equally probable octahedral positions forming the immediate environment[10]. Thus, atoms are unaccompanied by migrating oxygens, and diffusion now involves the movement of one non-metal for every two metal ions.

Fig. 4*a* represents the structure of high-temperature Nb_2O_5 (ref. 10); and Fig. 4*b*, $TiNb_{24}O_{62}$ or $Nb_{25}O_{62}$ (ref. 2). The tetrahedral atom 7 in the former moves to an octahedral position in the latter, octahedral Nb 10 to a tetrahedral site, while the niobium and oxygen atoms 8 and 9 move to adjoining positions of the same kind as those they previously occupied. The movements of atoms 10, 11 and 12 in Fig. 4*b* to octahedral sites and of 13 to tetrahedral give the structure of $Nb_{11}O_{27}$ (ref. 10). The re-oxidation at low temperatures of $Nb_{11}O_{27}$ and $Nb_{25}O_{62}$ to new forms of Nb_2O_5 involves little change in the X-ray powder patterns[11]. Evidently the shear planes do not move, and the gross structure remains intact. But the tetrahedral atoms are free to migrate in the *b* directions of both phases (out of the plane of the paper) by way of the alternate filled and empty tetrahedral positions present in these structures[2,10], and form a film of new oxide on reaching the surface. When the temperature of oxidation is raised, the oxygen atoms, and therefore the shear planes, move and follow the reverse paths of Figs. 4*a* and *b*, giving high-temperature Nb_2O_5 as the end-product.

It is noteworthy that the many perovskite compounds ABO_3, where BO_3 is the ReO_3-type host structure containing *A* ions in the holes, do not form related shear structures. We have repeatedly, and without success, attempted to synthesize 'defect' perovskites of this kind, and evidently diffusion cannot occur when the holes are filled. Unless the structure is deficient in *A*, there is no way for the shear planes to form, and unless these ions are largely absent, there is no way for the planes to propagate, unless they too move and are lost, either as a volatile compound or as a new foreign solid phase. Authentic anion-deficient perovskites are unknown and alternative structures form instead[12–14].

Shear planes are also present in the Ti_nO_{2n-1} phases. Here the terminal octahedra of adjacent blocks of rutile (TiO_2) structure share faces[15], and not edges and corners (Fig. 5). The unreduced rutile structure contains interstitial octahedral positions, and in the reduced phases these are filled by some of the metal atoms belonging to the adjacent block[1,15]. A diffusion mechanism for the formation of the planes by the reduction of rutile involves the transport of planes of metal ions into the

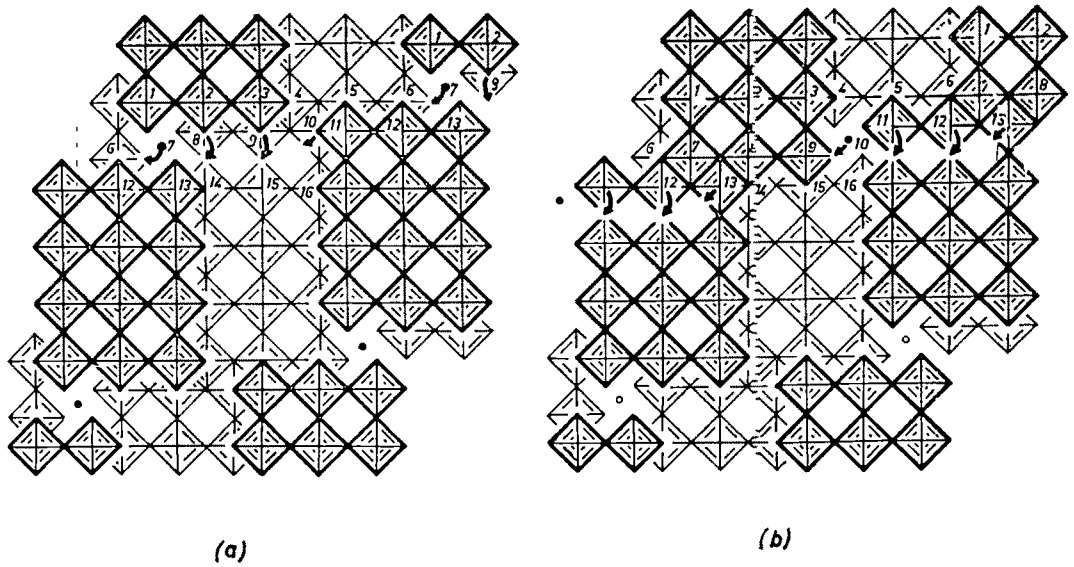

Fig. 4 *a* and *b*, Formation of $Nb_{22}O_{62}$ and $Nb_{12}O_{37}$ from Nb_2O_5 by the movement of a shear plane. *a*, Structure of high temperature Nb_2O_5. *b*, Structure of $Nb_{22}O_{62}$. The small black circles numbered 7 in *a* are tetrahedral metal ions which move (arrows) and form octahedra as in *b*. Niobium 10 moves from octahedral co-ordination in *a* to tetrahedral in *b*. The additional migrations indicated in *b* result in the structure of $Nb_{12}O_{37}$. Niobium 13 becomes tetrahedral in this latter structure and niobium 10 changes from tetrahedral to octahedral

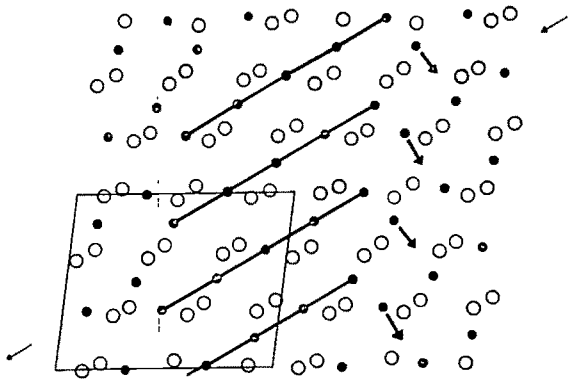

Fig. 5. Structure of Ti_5O_9. ●, Titanium; O, oxygen. The five titanium atoms joined by a thick line constitute a block of the rutile (TiO_2) structure, and the terminal octahedra share faces with those in the next block. The movement of the titanium atoms indicated by the arrows results in a block six titanium atoms long, which is characteristic of the next phase Ti_6O_{11} in the series Ti_nO_{2n-1}. The oxygens remain intact

next row of empty positions, each metal ion moving through a triangle of oxygens (an octahedral face) (Fig. 5) and no oxygen migration is possible. By close control of conditions, the oxidation of Ti_4O_7 ($n = 4$ of the series Ti_{2n-1}) to TiO_2 should result in the formation of each higher homologue ($n = 5$, 6, 7, etc.) in turn, and the inference that the shear planes have a high mobility in the solid is supported by the remarkable ciné films of reduced titanium dioxide, made by Eikum and Smallman in the electron microscope[16].

It is becoming increasingly evident that shear planes are a common feature in the higher oxides of the metals of Groups IV, V and VI. We believe that the properties of the phases in which they occur may well depend on their nature and mobility.

Elachistosuchus, A TRIASSIC RHYNCHOCEPHALIAN FROM GERMANY

By DR. A. D. WALKER

Department of Geology, University of Newcastle upon Tyne

Elachistosuchus huenei, a very small reptile with a skull some 26 mm long, from the late Keuper of Halberstadt near Magdeburg, was allocated to the Pseudosuchia by Janensch[1], on the grounds that it possesses a preorbital opening in a diapsid skull and thoracic vertebrae with "spectacle-shaped" rib articulations—this in spite of the acrodont dentition, large post-temporal fossae and lack of a mandibular fenestra. *Elachistosuchus* has been made the sole representative of a family and superfamily of the Pseudosuchia by Hoffstetter[2] and von Huene[3], the latter regarding it as a modified descendant of the Lower Triassic Proterosuchidae. It will be shown, however, that *Elachistosuchus* can be interpreted with greater probability as a rhynchocephalian, closely allied to the living *Sphenodon*.

Obviously the most important point to be established is the nature of the "preorbital opening". In *Elachistosuchus* (Fig. 1) a substantial part of the maxilla lies

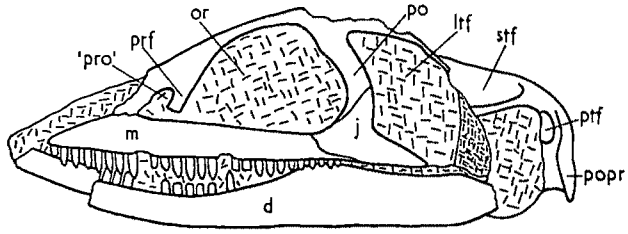

Fig. 1. *Elachistosuchus huenei* Janensch Left side of skull, × *c.* 2, after Janensch[1]. The posterior portion of the skull has been pushed downward and backward; the more heavily hatched area is a stain on the matrix representing the rear border of the lateral temporal fossa. Abbreviations for this and succeeding figures as in Romer[5], with the addition of *ltf:* lateral temporal fossa; *stf:* supratemporal fossa; *'pro':* preorbital opening of Janensch, herein identified as the lachrymal foramen

below the large orbit, and the bone ends posteriorly below the postorbital bar. This is quite unlike the situation in any pseudosuchian. Even in *Chasmatosaurus*[4], to which (among others) *Elachistosuchus* is compared by Janensch because of the acrodont dentition, the greater proportion of the maxilla lies below and in front of the preorbital fossa, this being the usual condition in the Pseudosuchia. In fact, the orbit of *Elachistosuchus* is rather like a pseudosuchian preorbital fossa, especially in the contribution made by the jugal, and I at first attempted a re-interpretation along these lines, but the arrangement of the more posterior openings in the skull makes such an explanation impossible.

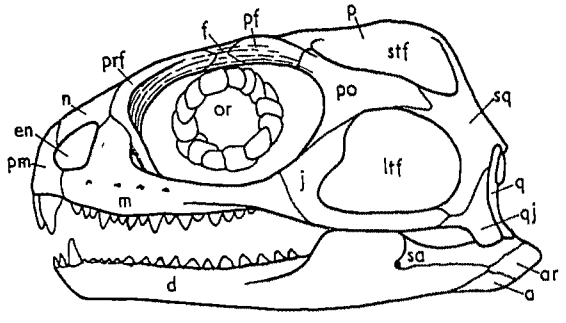

Fig. 2. *Sphenodon.* Left lateral view of skull, simplified from Romer[5], × *c.* 1

It is suggested that the key to the understanding of the skull of *Elachistosuchus* is supplied by the curious nature of the prefrontal in *Sphenodon*[5]. In this animal (Fig. 2) the lachrymal is missing and the prefrontal descends to the palate, passing medially within the anterior wall of the orbit and touching the palatine. In its lower course it encloses a large foramen ("canalis maxillare"[6] or lachrymal canal) between it and the ascending process of the maxilla. This arrangement is not homologous with the archosaurian preorbital fossa, the latter being bounded by the maxilla and lachrymal, with the jugal forming only a small part at the posterior inferior corner, and the prefrontal not entering at all. It is virtually certain that the so-called "preorbital fossa" of *Elachistosuchus* is really the lachrymal canal, since its relationships are practically identical with those in *Sphenodon*: a descending process from the skull roof at the position of the prefrontal forms its posterior border, and it is bounded in front by the ascending process of the maxilla (Fig. 3). Janensch's assumption that the right side shows this aperture more accurately is probably incorrect, since the left side of the skull is less distorted, the right having been pushed backward, according to that author. Thus it seems to have been a much smaller opening than is the case in most preorbital fossae, though nevertheless apparently larger than the lachrymal foramen in living *Sphenodon*. However, a posteroventral compression of the anterior part of the skull roof might account for the enlargement of the foramen and the difference in attitude of the prefrontal as compared with that of *Sphenodon*.

In *Sphenodon* again the jugal has a long anterior process lying in the floor of the orbit, concealed by the maxilla in side view, and reaching to within 2 mm of the prefrontal. Exactly such an arrangement occurs on the right side of the skull of *Elachistosuchus* (Fig. 3), but an anterior process of this type does not occur in Pseudosuchia, nor probably in any archosaur. The sutures between the jugal, maxilla and postorbital are, in fact, closely similar in *Sphenodon* and *Elachistosuchus*.

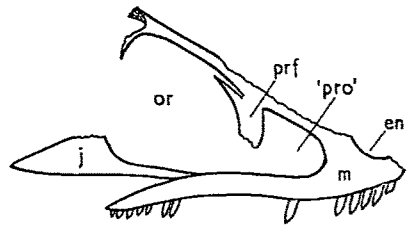

Fig 3. *Elachistosuchus.* Right side of facial part of skull, after Janensch, × *c.* 2

Other features which are anomalous for a pseudosuchian, but apt for a rhynchocephalian, may be dealt with briefly. These are: (*a*) the numerous acrodont, isodont teeth; (*b*) the very large post-temporal fossae and narrow supraoccipital (Fig. 4); (*c*) lack of a mandibular fossa (unusual in an Upper Triassic pseudosuchian); (*d*) low position of the paroccipital process, well below the upper temporal arch; (*e*) weak coronoid process (although stated by Janensch to be absent); (*f*) presence of a notch for the external naris at the anterior margin of the maxilla (Fig. 3)—in pseudosuchians the naris is either further forward or the maxilla curves smoothly upwards. Janensch (ref. 1, p. 227) also refers to a "bent down" fragment of the upper jaw at the anterior tip of the skull on the right side, which he suggests may represent the premaxilla. This would seem highly likely to be a rhynchocephalian "beak". The relatively short humerus with its strongly expanded extremities set almost at right angles to each other recalls the primitive "twist" retained in *Sphenodon*; the entepicondyle is very well developed. The lack of dermal ossifications is not conclusive, since they are not ubiquitous in the Pseudosuchia.

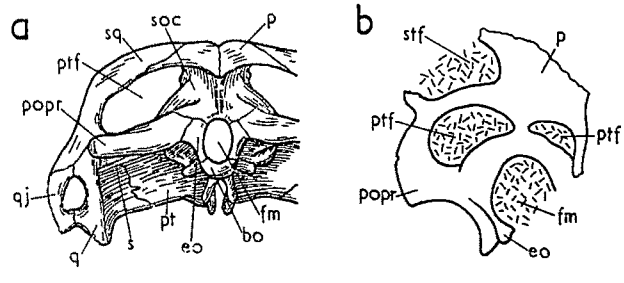

Fig. 4. Occipital views of *a Sphenodon*, after Romer, × *c.* 1; *b: Elachistosuchus*, after Janensch, × *c.* 2

There remain to be considered the vertebrae and their articulations with the ribs. Intercentra are present throughout the presacral series in *Sphenodon*, and though absent in the preserved vertebrae of *Elachistosuchus*,

this is not a bar to the affinities suggested here, since *Homoeosaurus*, a sphenodontid from the Upper Jurassic[2], lacks intercentra in the trunk region, and so probably does *Brachyrhinodon*[7] from the Upper Trias of Elgin, Scotland. The elongated, distinctly curved "cervical" ribs described by Janensch are more probably thoracic ribs, and his "block II" is thought more likely to succeed, rather than precede, "block III" because of the nature of the rib articulations; it does not necessarily follow that the vertebrae increase in size towards the sacrum, as they normally do in the Pseudosuchia, hence the preserved vertebrae probably include only the more posterior cervicals. The double rib-facets of *Elachistosuchus*, furthermore, are not strictly comparable to the "spectacle-shaped" articular areas seen in some pseudosuchians[8], or in *Ornithosuchus*[9], for when in the posterior thoracics the rib-facets become confluent (due to the gradual reduction in length of the diapophyses), they also come to lie almost on the same level, whereas in *Elachistosuchus* the parapophysis is distinctly below the diapophysis, although the two processes are virtually the same length. The most complete vertebra illustrated by Janensch (ref. 1, Figs. 6–8), which is probably the most anterior preserved, has, in fact, rib-facets which are very like those of the eighth cervical vertebra of *Sphenodon* (ref. 6, Fig. 19).

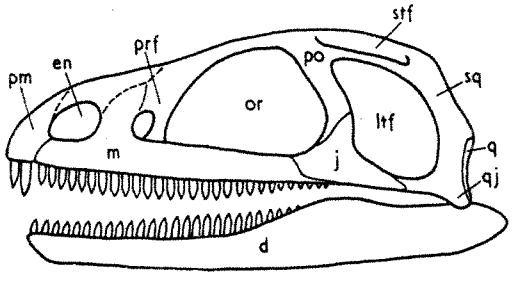

Fig. 5. Suggested restoration of the skull of *Elachistosuchus*, × *c.* 2. On the whole the restoration by Janensch[1] has been followed, but the quadrate and snout regions have been modified; no attempt has been made to correct for possible distortion of the prefrontal. The jaw has been moved back slightly on the ground that the coronoid process should pass up behind the lower temporal bar; this also gives a better fit with the premaxilla

Inasmuch as the lower temporal bar is not demonstrably complete in *Elachistosuchus*, due to the loss of the quadrato-jugal in the fossil, the possibility of lacertilian relationships cannot be excluded. In lizards also the prefrontal descends to the palatine, the lachrymal may be lost (although this is a relatively modern specialization; *Kuehneosaurus*[10], from the Upper Keuper, for example, has a large lachrymal), the post-temporal fossae are frequently large, and the jugal may have a long anterior process below the orbit (but visible in this case from the side), see *Iguana*, for example. The large number (twenty-eight) of small cylindrical teeth in *Elachistosuchus* is also rather lizard-like. On the other hand there is no reason to doubt that the lower arcade was originally complete, especially as the missing portion is extremely short. The acrodont implantation is suggestive, but not conclusive, of rhynchocephalian affinities. In particular the arrangement of the prefrontal, maxilla and jugal with respect to the orbit is extremely like that of *Sphenodon* and, in detail, unlike any lizard; the occiput is closer to that of *Sphenodon*, even the form of the foramen magnum (Fig. 4) being quite similar. When to these points is added the bicipital nature of the posterior cervical and/or anterior dorsal ribs, the form of the humerus and the possibility of a "beak", little doubt can remain of the rhynchocephalian nature of *Elachistosuchus*.

The superfamily Elachistosuchoidea may thus, with some satisfaction, be discarded, for *Elachistosuchus* may certainly be placed within the Sphenodontidae. It displays features of the skull and vertebrae so far undescribed or imperfectly revealed in the few Triassic genera which are available. These include the ventral extension of the prefrontal, the probable loss of the lachrymal, the relationships of the jugal with neighbouring bones, and the construction of the occiput. These details have survived with virtually no change since Upper Triassic times and add further emphasis to the already well known conservatism of the living *Sphenodon*.

Von Huene[3] divided the Sphenodontidae into the subfamilies Brachyrhinodontinae (Triassic), Monjurosuchinae (Jurassic) and Sphenodontinae (Jurassic to Recent), placing *Homoeosaurus*, however, as the type of a separate family. *Elachistosuchus* differs from *Sphenodon* and resembles *Homoeosaurus*[11], *Polysphenodon* from the Middle Keuper near Hannover[12], and *Brachyrhinodon* in that the parietals form a flat surface between the supratemporal fossae, their breadth here equalling or exceeding that between the orbits. It appears, therefore, that the narrow parietal crest of the living form is, as one might expect, a relatively modern specialization. The lachrymal had probably been lost in *Polysphenodon*, and perhaps also in *Brachyrhinodon*. My present work indicates that these two are extremely closely related, if not actually congeneric; von Huene[3] paradoxically reversed his previous opinion[2] and placed *Polysphenodon* in the Rhynchosauridae, in spite of its paired, terminal external nares and other differences. *Elachistosuchus* differs from these two genera in the more posterior position of the orbit, the less flattened and more lightly built skull, the more numerous teeth, and the lack of a marked coronoid process. Other Triassic genera are too imperfectly known at present for profitable comparison, the teeth of *Clevosaurus*[13], and *Palaeorodon*[14], evidently being very different. Although lacking intercentra in the thoracic region, *Elachistosuchus* is considered to be best placed in the subfamily Sphenodontinae, because of the close resemblance of the skull to that of *Sphenodon* itself. Janensch[1] regarded the dentition as being of an unspecialized type suitable for dealing with "small animals, arthropods, worms, etc." and also plant food. The relatively broad area between the supratemporal fossae, and the weak coronoid process, may reasonably be viewed as primitive features retained from a late Permian or early Triassic eosuchian ancestor in connexion with a likewise unspecialized jaw musculature. Hence *Elachistosuchus* presumably represents an extremely primitive rhynchocephalian stock, while the approximately contemporaneous Brachyrhinodontinae are a slightly more specialized side branch. Furthermore, if, as is possible, the premaxillary teeth of *Elachistosuchus* were similar to those of the maxilla (that is, it lacked the typical rhynchocephalian development) and, like *Polysphenodon*[15] and *Brachyrhinodon*, there were rows of teeth on the pterygoid as well as on the palatine, then we would have here a form structurally close to the common ancestry of Rhynchocephalia and Squamata.

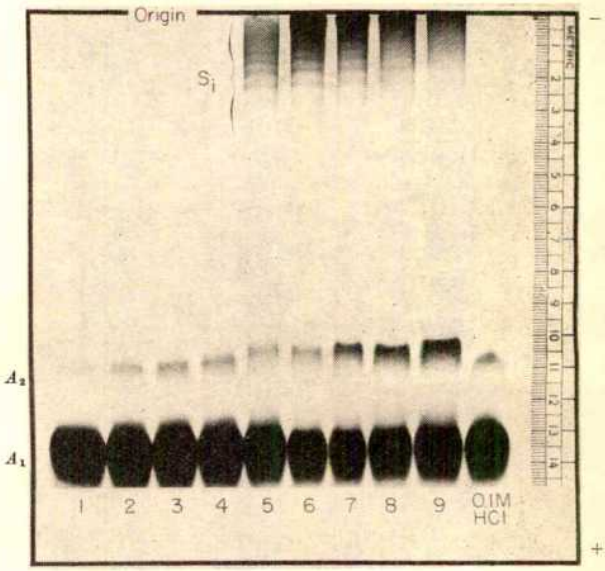
KINETICS AND MECHANISM OF ALBUMIN DENATURATION

By THOMAS G. FERRIS

Rear Admiral George W. Calver's Physical Chemistry Research Laboratory, U.S. Naval Medical School

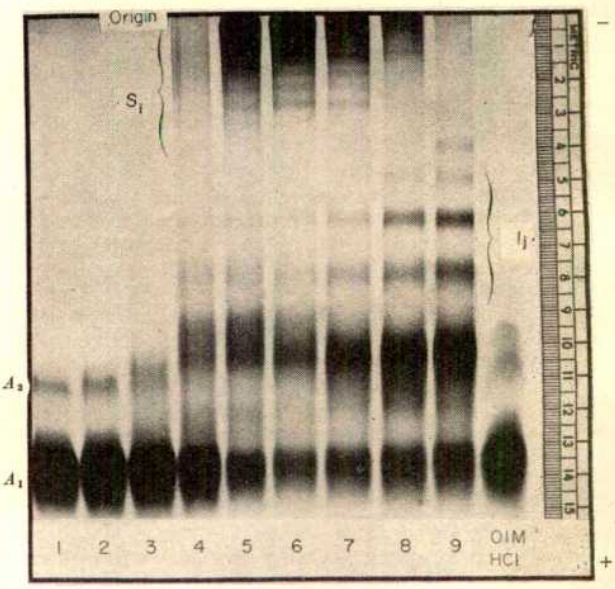
AND



SAM KATZ*

Naval Medical Research Institute, National Naval Medical Center, Bethesda, Maryland

THE ability of acrylamide gel zone electrophoresis to resolve protein sub-species which differ only in respect of charge, molecular weight and, possibly, conformation[1], coupled with the ability to quantitate the resultant patterns with a specially designed densitometer[2], prompted us to investigate the denaturation of bovine serum albumin (BSA) by urea. The objective was to investigate the kinetics of the denaturation process, and then to relate the various mechanisms to the structural determinants which define the geometry of the macromolecule in a given medium.



The denaturation procedure was conventional, using 10 mg of BSA (Armour and Co.) dissolved in 0·25 ml. of urea solution prepared from recrystallized urea (Mallinkrodt)[3]. Acrylamide gel zone electrophoresis was carried out on a vertical electrophoresis cell (Model 500, Arden Instruments, Inc., Rockville, Maryland) capable of the simultaneous analysis of thirty samples, using the gel slab technique. Sample volumes ranged from 10–50 μl. The supporting medium was 5 per cent 'Cyanogum 41' (American Cyanamid Co.) prepared with a *tris*-EDTA-boric acid buffer, *p*H 8·3, which also served as the electrolyte for electrophoresis[4]. Reversibility experiments involved the addition of 2 volumes of water to the denaturation system to stop the reaction. The urea was then removed by thin-film dialysis for 24 h against several changes of water. Evidence that the electrophoretic patterns produced by the denatured BSA were not artefacts was supported by the reproducibility of the results obtained using either the standard buffer or the buffer containing 3 M urea as the electrolyte for electrophoresis.

The effect of varying time and urea concentration is typified by the following systems in which BSA was exposed to 1–9 M urea at room temperature for 4 min and for 24 h before electrophoresis (see Figs. 1–4). A fast reaction occurs within 4 min at urea concentrations greater than or equal to 5 M, which produces a series of components, S_i, characterized by electrophoretic mobilities ranging from 0–30 per cent of that of the fastest component, A_1 (Fig. 1). The formation of the S_i fractions is associated with a concomitant decrease in the A_1 component (Fig. 3). With an increase in time and urea concentration there is a reduction in the S_1 fractions and the appearance of a new set of fractions, I_j, with mobilities intermediate to the A_1 and S_1 components (Figs. 2 and 4). The predominant species present in the system containing BSA exposed to 9 M urea for 24 h is a fraction with a mobility almost identical to A_2, a constituent found in the BSA before urea denaturation. Reversibility experiments using BSA exposed to 8 M urea for periods of time extending from 4 min – 24 h showed a linear relationship between the amount of water-insoluble protein produced with the length of urea contact time. During the course of dialysis the S_i fractions initially present disappeared with the appearance of the I_j fractions. The temperature dependence for denaturation was positive. The rate at 37° C was about ten-fold greater than that observed at 4° C. The *p*H rate dependence resembled a skewed

geometric function with the maximal rate in the alkaline region; at *p*H 1·7 the rate was about five times as great as that found at neutrality, while at *p*H 10 it was greater by at least two orders of magnitude. The products produced by these systems were electrophoretically indistinguishable from each other. This was in contrast to the acid or alkali denatured BSA (exposed to 0·1 M reagents) the patterns of which differed in a characteristic way from each other and from the urea-denatured albumin.

A detailed discussion of the kinetics and reaction mechanisms will not be attempted, but a few of the salient features will be mentioned. Urea denaturation is initiated by a fast reaction involving conformational changes with the appearance of the S_f fractions. This is followed by a decrease in the S_f fractions which is due either to their conversion to components with zero mobility or to their transformation to the I_f fractions (Figs. 2 and 4). There is evidence that certain of the I_f fractions can be produced directly without passage through the intermediate or short-lived S_f state. On the basis of the distinctive electrophoretic patterns and reaction rates it is evident that the mechanisms for urea, acid, alkali and heat denaturation must differ substantially from each other.

The characteristic mobilities observed for the several species of denatured albumin can be attributed to any or a combination of the following factors. The values for the prototropic dissociation constants of the protein can be altered by the change in the macromolecular conformation or by the increase of the dielectric constant of the system on the addition of urea[6], thus producing a shift in the net charge on the protein and in its affinity for buffer ions. The transformation of albumin from the native globular form to a random configuration with an increased axial ratio results in a commensurate increase of frictional resistance to transport processes and in the subsequent reduction in electrophoretic mobility[6]. Another contributing factor is the slow time-dependent polymerization process that occurs during denaturation and produces substantial changes in both the molecular geometry and charge[7].

We hope to isolate, characterize, and establish the structural features that determine the electrophoretic

properties of the various fractions resolved by this technique.

We thank R. E. Easterling, K. J. Nelson and R. E. Budd for their invaluable technical assistance.

IONIC COMPLEXES OF THIOUREA

By DR. J. C. A. BOEYENS and PROF. F. H. HERBSTEIN*

Chemical Physics Group of the National Physical and Chemical Research Laboratories, Council for Scientific and Industrial Research, Pretoria

THIOUREA is one of the most versatile complexing agents yet discovered. It forms the well-known inclusion complexes with branched-chain hydrocarbons[1] and also has the ability to complex with various other organic substances[2] and with some salts of virtually every metal.

This latter property is largely a result of the formation of covalent sulphur-to-metal bonds[3]. However, thiourea has also been reported to form stable complexes with salts of elements which do not form covalent bonds to co-ordinated ligands. Another explanation must be sought for the existence of these complexes.

The prototype of these thiourea complexes is $NH_4Br.4TU$ (TU, thiourea), first described by Reynolds in 1888 [4]. The isostructural series includes the complexes formed with some halides of potassium, rubidium and caesium, with many ammonium and thallium (I) salts and with some lead (II) salts. These are all stoichiometric complexes and, depending on the oxidation number of both cation and anion, they have the general formulae:

$$MX.4\,TU$$
$$M_2X.8\,TU$$
$$MX_2.6\,TU$$

The nature of this family of complexes has now been established by a correlated chemical and crystallographic investigation. The preparations reported in the literature have been repeated and checked and some new complexes have been prepared. All the complexes have been examined by single-crystal or powder X-ray diffraction techniques and the unit-cell dimensions, space group and density (of single crystals only) determined. This has enabled some thirty-odd related complexes to be further subdivided into groups of isomorphous or nearly isomorphous structures. Representative complexes from each group were then chosen for structural analysis, thus enabling the relationship between the groups to be established. Some measure of disorder appears to be a feature of many of the structures at room temperature. While this has prevented determination of all the details of the structures, their main outlines have been settled. A broad survey and general description of the results obtained will be given in this article, to be followed by a series of more detailed papers now in preparation.

Classification of the Complexes

Morphologically the solid complexes are usually fibrous masses and only in some cases could single crystals suitable for crystallographic work be obtained. Well-defined X-ray powder patterns have, however, always been obtained.

The unit-cell dimensions and space groups show that the complexes fall into a number of well-defined groups. The largest of these includes the 1 : 4 complexes of alkali bromides and iodides, thallium (I) bromide, iodide and perchlorate. These crystals are all tetragonal with $a \sim 20$ Å, $c \sim 8{\cdot}3$ Å and space group $P4/mnc$. Closely related to these is a smaller group of complexes, including the thallium (I) nitrate, and sulphate (1 : 8) complexes, which have $a \sim 10$ Å, $c \sim 8{\cdot}3$ Å, space group $P4/mcc$. A Weissenberg photograph of the $TlNO_3.4$ TU complex at $-160°$ C showed that at this temperature this complex had $a \sim 20$ Å, $c \sim 8{\cdot}3$ Å and space group $P4/mnc$. Thus the smaller unit cell appears to be a partially disordered version of the larger ordered cell; this was established in detail by determining the structures of $TlClO_4.4$ TU and $TlNO_3.4$ TU at room temperature (the super-lattice reflexions of the latter are too weak even at $-160°$ C to allow reliable determination of the differences between the partially disordered and the ordered version of this structure). Two other ordered structures have been obtained. In one of these $a \sim b \sim 14$ Å, $c \sim 8{\cdot}3$ Å, while in the other $a \sim 2b \sim 21$ Å, $c \sim 8{\cdot}2$ Å. These structures, which have not been determined, would be expected to differ in detail only from that of $TlClO_4.4$ TU.

Another group is formed by the complexes of the alkali and thallium (I) chlorides, which have $a \sim 32$ Å, $b \sim 13$ Å, $c \sim 8{\cdot}5$ Å and space group $Bbam$ (this is the orientation most convenient for comparison with the other complexes). These complexes have only been obtained in polycrystalline (fibrous) form but one fluoride complex, $CsF.4$ TU. $2\,H_2O$ has cell dimensions ($a \sim 17{\cdot}0$ Å, $b \sim 12{\cdot}5$ Å, $c \sim 8{\cdot}45$ Å, space group $Ibam$, four formula units per unit cell) which are closely related to those of the chloride complexes. Single crystals of this fluoride complex have only been obtained recently and its structure has not yet been determined.

All the complexes discussed until now have been of thiourea with salts of monovalent metals, but two related complexes of divalent lead salts have also been reported: these are $Pb(NO_3)_2.6$ TU[5] and $Pb(ClO_4)_2.6$ TU[6]. Crystallographic investigations have shown that these two complexes also belong to this general family despite the difference in the ratio of cations to thiourea molecules. Both complexes have partially disordered structures (of different types) at room temperature, but X-ray structure analysis has revealed the general outlines of their structures and in particular has shown how a cation : thiourea ratio of 1 : 6 is possible.

The structural results will now be described in more detail. Some of the structures have been analysed by three-dimensional methods and some by two-dimensional methods; intensities were measured visually from Weissenberg photographs taken with copper $K\alpha$ radiation. The structures were generally solved by Patterson methods and refined by Fourier and least-square techniques. The R-factors are all below 12 per cent and there are no

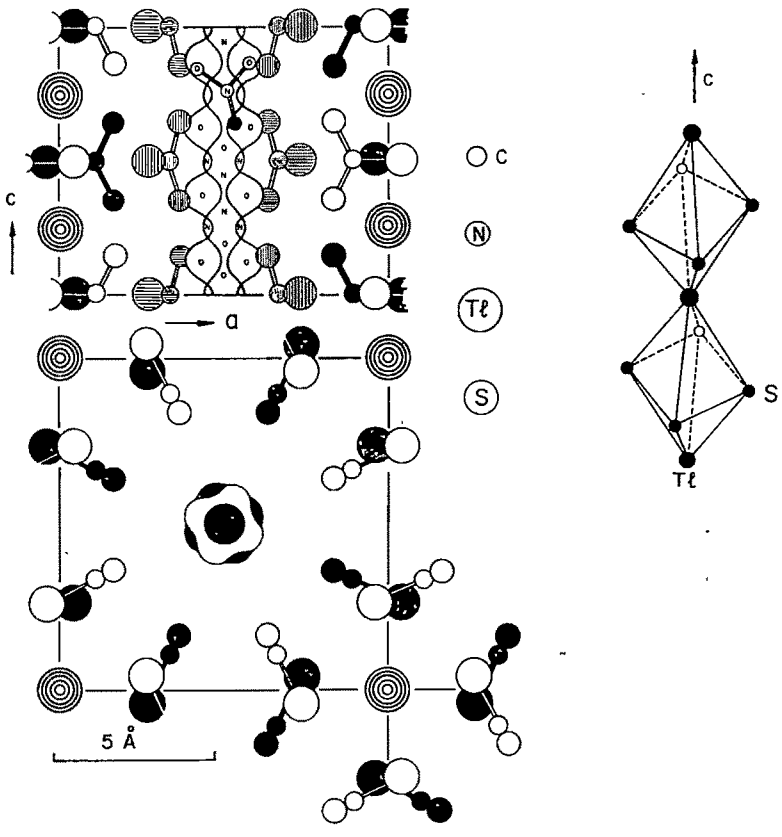

Fig 1 The crystal structure of the $TlNO_3$.4 TU complex shown in projection down [001] and [010]. On the right the arrangement of sulphur atoms and thallium ions in one of the chains along [001] is shown. In the projection down [001] the atoms represented by full circles lie in the plane of the paper while those represented by open circles are in the mirror plane lying $c/2$ above or below the plane of the paper. In the [010] projection the full-circle molecules lie about $a/4$ below the plane of the paper while those with open circles lie the same distance above it. The horizontally shaded molecules are about $a/2$ below the plane of the paper and the vertically shaded molecules the same distance above it

outstanding discrepancies between observed and calculated structure factors.

Structure of $TlNO_3$.4 TU

These crystals have $a = 10{\cdot}34$ Å, $c = 8{\cdot}29$ Å, space group $P4/mcc$, two formula units per unit cell. The results of the crystal-structure analysis are summarized in Fig. 1. The essential feature of this structure type, and the family as a whole, is the existence of separated cations and anions bridged by polar thiourea molecules. Each cation is surrounded by eight sulphur atoms at the corners of a distorted cube centring on the cation site (Fig. 1, right). The average thallium–sulphur distance is 3·43 Å, which is considerably longer than the separation between sulphur atoms of co-ordinated ligands and metal atoms. Indeed, the sum of the atomic radii of thallium and sulphur is about 2·7 Å whereas the sum of their ionic radii is about 3·3 Å. Thus it is clear that these are ionic complexes and that the major cohesive interactions in the crystals are ion-dipole interactions. The arrangement shown in Fig. 1 can be described as a linear chain of metal ions surrounded by neutral but polar thiourea molecules with the sulphur atoms of a set of thiourea molecules bridging successive cations. The separation between neighbouring cations in a chain is 0·5 c, or approximately 4·1 Å.

The thiourea molecules point away from the arrays of cations situated along the four [001] edges of the unit cell and in this way they enclose a cylindrical channel with its axis along $[\frac{1}{2}\frac{1}{2}z]$. The anions are in these channels and in an idealized structure would lie along the cylinder axis which is also a crystallographic four-fold axis. In the crystals that have been investigated the anions have lower symmetry and hence are disordered positionally. This type of structure is not directly comparable with the channel structures of the thiourea–hydrocarbon complexes since the thiourea molecules are not connected through S...H—N hydrogen bonds.

The structures of a number of crystals are known in which similar, approximately cubic arrangements of sulphur atoms about potassium and ammonium ions are found (for review see Wells[7]), while another close comparison can be made with the arrangement in thallosothallic sulphide, $Tl_2^{III}S_3.Tl_2^{I}S$ (refs. 8, 9, also ref. 7, pp. 900–901). The thallium (III) atoms in this structure are linked by sulphur atoms ($d(S\text{-}Tl^{III}) \sim 2{\cdot}6$ Å) to form chains of tetrahedra sharing opposite edges, while the thallium (I) atoms lie between the chains with eight sulphurs around them ($d(S\text{-}Tl^{I}) \sim 3{\cdot}3$ Å). The interactions between the sulphur and thallium (I) atoms appear to be ionic interactions somewhat similar to those found in the present family of complexes (however, ion-dipole forces are unlikely to be important in TlS).

Ordered Structure as found in $TlClO_4$.4 TU

These crystals have $a = 21{\cdot}07$ Å, $c = 8{\cdot}28$ Å, space group $P4/mnc$, eight formula units per unit cell. Their structure, which is characteristic of the majority of these complexes, differs from the $TlNO_3$.4 TU structure in that two neighbouring cation–thiourea chains are not crystallographically equivalent but are rotated to a small extent relative to one another and have slightly different ($\sim 0{\cdot}05$ Å) thallium positions; the doubling of the a axis is a consequence of these differences. The space group no longer requires the anions to lie on the axis of the cylindrical channel.

The structural details of the $TlClO_4$ and $TlNO_3$ complexes provide the key to most of the general crystallographic properties of the ionic thiourea complexes. In particular an explanation is provided for the fact that most of the complexes crystallize with a unit cell having $a \sim 20$ Å while the strongest reflexions define a sub-cell with $a \sim 10$ Å. If only the sub-cell is considered, both the cations and anions will be arranged in a linear chain with periodicity $c/2$. This is possible only if the distances between neighbouring cations and neighbouring anions are fortuitously the same. In the general case, therefore, the anionic arrangement is non-linear. This causes slight distortion of the cylindrical anionic channel of the sub-cell and the appearance of the superstructure. In the nitrate complex the deviation of the anionic chain from linearity is either masked by rotational disorder or else is so slight that it is beyond the limits of detection, but in the $TlClO_4$.4 TU structure the perchlorate tetrahedra are in an ordered array and displaced off the cylinder axis.

Complexes of Divalent Metal Salts

The complexes of this family formed by the salts of divalent metals (lead is the only known example) are essentially isostructural with the complexes of monovalent metal salts. The 1 : 6 ratio encountered in these complexes can arise in one of two ways, exemplified by the structures of the $Pb(NO_3)_2$ and $Pb(ClO_4)_2$ complexes.

Structure of the $Pb(NO_3)_2$.6 TU Complex

This complex caused some controversy in the past. It was described first by Rosenheim and Meyer[5], who assigned to it the formula $2Pb(NO_3)_2$.11 TU. The analytical work of Mahr and Ohle[6] supported the 2 : 11 ratio, but Brú *et al.*[10] concluded from crystallographic considerations that the most probable formula was 6 $Pb(NO_3)_2$.32 TU. However, the experimental crystal density of 2·03 g/cm³ is in good agreement with the 1 : 6 ratio deduced by Haworth and Mann[11] from their analytical results, but not with the densities calculated on the basis of the other proposed compositions. We have therefore used the 1 : 6 formulation. It should be emphasized that the crystal structure at room temperature is such that the $Pb(NO_3)_2$: thiourea ratio is not determined by space group considerations (in contrast, for example, to the 1 : 4 ratio in the $TlNO_3$ complex) and is not necessarily rational. The value used is an experimental value derived from chemical analyses and density measurements.

The complex has the space group *P4/mcc* characteristic of the $TlNO_3$.4 TU structure type. It has also $a = 10{\cdot}3$ Å, but $c = 24{\cdot}6$ Å, which is three times the *c*-axis of the other structures. There are four formula units per unit cell. Oscillation photographs about [001] show additional diffuse layer lines which indicate that there is considerable disorder in the structure. This has not been explained in detail. The electron-density projection down [001] is very similar to that obtained for $TlNO_3$.4 TU and this shows that the atomic arrangement must be essentially the same in both complexes. The suggestion of Brú[12] that this structure consists of an ordered framework of thiourea molecules which has tubular cavities in which lead nitrate molecules are contained is not correct.

Structure of the $Pb(ClO_4)_2$.6 TU Complexes

The $Pb(ClO_4)_2$.6 TU crystals have $a = 18{\cdot}6$ Å, $c = 7{\cdot}92$ Å, space group *P4/mcc*, four formula units per unit cell. The structure is based on that of the $TlClO_4$.4 TU complex, there being similar cation–thiourea chains along the cell edges and the central axis of the cell. The anion arrangements are also very similar. However, the cation sites along $[0\frac{1}{2}z]$ and $[\frac{1}{2}0z]$ are entirely vacant and these regions of the crystal contain half as many thiourea molecules as are in a cation–thiourea chain.

Water molecules can diffuse into these relatively open channels to give the hydrated complex $Pb(ClO_4)_2$.6 TU. 2 H_2O. The cell dimensions remain essentially unchanged when water is taken up in the structure, but the space group changes from *P4/mcc* to *I4/mcm*. A Fourier projection down [001] shows that the water and thiourea molecules in the regions about the empty channels are unresolved and it seems probable that what order there was in the positions of these thiourea molecules in the anhydrous crystals has become disrupted by the intruding water molecules.

Comparison of Structures of 1 : 4 and 1 : 6 Complexes

In the $TlNO_3$.4 TU complex there are two nitrate ions in each channel for each repeat distance of 8·2 Å along [001]; these ions do not completely fill the available space. In the $Pb(NO_3)_2$.6 TU complex there are eight nitrate ions in each channel for each repeat distance of 24·6 Å, or $2\frac{2}{3}$ per 8·2 Å. The available space in the channel is now completely filled. The requirements of stoichiometry result in there being four Pb^{++} ions to be distributed among the six cation sites of the one independent cation-molecule chain in each unit cell. Vacant cation sites result, the occurrence of diffuse scattering suggesting that these are not randomly arranged. The alternative of filling all cation sites in one set of chains and one-third of the cation sites in a second, non-equivalent, set is not used in this complex, presumably for both energetic and entropy reasons.

In the $Pb(ClO_4)_2$.6 TU complex quite a different means of compensating for the bivalent nature of the cations is used. The density of packing of perchlorate ions is much the same in the $TlClO_4$ and $Pb(ClO_4)_2$ complexes. In the $TlClO_4$.4 TU structure there are four Tl^+ ions for the two pairs of cation sites in the two crystallographically independent cation–molecule chains in the unit cell, but in a hypothetical $Pb(ClO_4)_2$ complex of the same structure there would be only two Pb^{++} ions for the four cation sites. Instead of half-filling all the sites in both chains, all the sites in one chain are filled and the other chain disappears. In its place one finds two thiourea molecules per unit cell (for the anhydrous complex) or two thiourea molecules and two water molecules (for the hydrated complex). These molecules do not appear to have any structural role in the crystals other than to fill space in the channels that exist in the loosely-bound framework formed by the cation–molecule chains and perchlorate ions. The differences in the two structures therefore stem from the different sizes of the nitrate and perchlorate ions.

Relationship of Other Complexes

The structures of a number of other complexes are known where a polar molecule forms a bridge between separated cations and anions. The greatest resemblance to the ionic thiourea complexes is shown by the ionic complexes $NaI.3(CH_3)_2NCHO$[12], $NaI.3(CH_3)_2CO$[13] and $NaI.3CH_3OH$[14]. These complexes all crystallize in hexagonal crystals and have similar structures. In the acetone complex, for example, there are chains of composition $(Na^+.3CH_3)_2CO$ running up the [00.1] axis. The iodide ions are in ordered positions in the channels between the hexagonally-arranged chains. Within a chain each Na^+ ion is surrounded by an octahedral arrangement of oxygen atoms of the carbonyl group while the methyl groups form the walls of the anion channel.

The approximately cubic and octahedral arrangements of sulphur and oxygen atoms about the cations of their respective complexes are in agreement with previous crystal-chemical results and can be explained in terms of the ratio of the radii of the ions involved (Pauling's[16] first rule). If comparable thiourea complexes of sodium salts can be prepared, then they will be expected to have an octahedral arrangement of sulphurs about sodium and thus will not belong to the present family of thiourea complexes. Similarly, complexes of oxygen-containing molecules with cations other than lithium and sodium will be expected to favour a cubic and not an octahedral arrangement of oxygen about the cations and thus differ from the complexes investigated by Piret *et al.*[15]. The fact that the crystals of the oxygen-containing molecules with sodium iodide favour hexagonal symmetry and those of the present thiourea complexes tetragonal symmetry follows from the respective octahedral and cubic arrangements in their cation–molecule chains.

ELECTROPHORETIC MOBILITIES OF PEPTIDES ON PAPER AND THEIR USE IN THE DETERMINATION OF AMIDE GROUPS

By R. E. OFFORD

Medical Research Council Laboratory of Molecular Biology, Hills Road, Cambridge

A SIMPLE model for the electrophoretic migration of molecules is of a sphere in an infinite medium impelled by electrostatic attraction and retarded by viscosity. It will then reach a terminal velocity, v, given by Stokes's law, and it can be shown (for example, ref. 1) that in this case, if the net electrostatic charge is ε, the radius of the molecule is r, the viscosity of the medium is η and the intensity of the electrostatic field is $-X$, then:

$$v = \frac{\varepsilon X}{6\pi r\eta} \quad (1)$$

The mobility, m, relative to some standard molecule run under identical conditions might then be given by a relation of the form:

$$m = k\varepsilon M^{-1/3} \quad (2)$$

where k is a constant and M is the mass of the molecule, the dimensional equivalent of r^3.

There are several difficulties in applying this model to practical situations. This is so for paper electrophoresis even after it has been noted that a correction is necessary due to the fact that the tortuous path taken by the molecule around the fibres of the paper makes the true potential gradient less than that which would be obtained by dividing the applied voltage by the straight line distance between the electrodes[2]. If, for example, the medium were not to be effectively infinite, a new treatment would be called for. In the limiting case, let it be supposed that the molecules were always very close to the fibres, or that retardation were to occur because the ionic atmosphere, being of opposite charge and solvated, causes a backward flow of solvent in the immediate vicinity of the migrating molecule. The retarding force could then be considered as the result of shear across a small element of liquid close to the migrating molecule. This would then be some function of the effective surface area of the molecule, in which case one might write:

$$m = k'\varepsilon M^{-2/3} \quad (3)$$

as area is dimensionally equivalent to $(\text{mass})^{2/3}$.

A number of important factors are neglected in both these models, in particular the possible contribution of the ionic atmosphere to the effective mass, and factors due to shape. They are simply mentioned as examples of the type of approach which might be adopted in order to rationalize actual experimental results without seeking a complete analysis of this very complex situation. Both types of model are examined with great mathematical rigour by Meuller[3]. Nevertheless, in an attempt to see if either of these crude models gave an answer near to the truth, relative mobilities were calculated for a large number of peptides. The experimental data came partly from records of preparative electrophoreses carried out in the course of sequential analysis of the coat protein of tobacco rattle virus (Offord, to be published), but also from similar and more extensive records obtained over some years by other workers in this laboratory (see final paragraph). These related to the determination of amino-acid sequences in chymotrypsin, elastase, cytochrome b_{551}, insulin from various animals, some Bence-Jones proteins, myosin, and glyceraldehyde phosphate dehydrogenase. The peptides contained only the usual L amino-acids except for the fact that cysteine and cystine had been converted to cysteic acid before running and that methionine was occasionally in the form $MetSO_2$.

The buffer system selected for investigation was pyridine–acetic acid–water 25 : 1 : 225 by volume (ionic strength about 0·07) and the paper, which hung vertically in an apparatus similar to that of Michl[4], was cooled by toluene–pyridine 23 : 2 (v/v). This arrangement corresponds to a pH of about 3·5 at which most groups that can be ionized—except the imidazoyl of histidine—would be expected either to be fully charged or fully discharged.

It was found that all records included reference to the migration of marker substances (usually the free amino-acids). An attempt was therefore made to correct for differences in mobility due to variations in ambient temperature and any other conditions by expressing all results relative to the mobility of free aspartic acid during the same run. Even if, as was occasionally the case, m had first to be expressed in terms of some other marker and then normalized, the values obtained have been shown to be repeatable to about ± 5 per cent over the range of temperatures (10°–40° C) experienced here. The position of the origin did not greatly matter, particularly as any disturbance in the mobility of a fast-moving spot on approaching the electrode troughs was usually matched to some extent by a similar effect on a marker. Endosmosis is quite considerable in this system (1–2 cm toward the cathode after 1 h at 3 kV) and the point of zero mobility was taken to be the mid-point of the free neutral amino-acid spot. Such a precaution is essential as peptides which are clearly neutral have sometimes been described as cationic, and anionic peptides as neutral (for example, ref. 5). The position of the leading edge of a migrating spot is the one best recorded; experiment shows that it is far less affected by overloading than that of the mid-point. Where possible, this was kept in mind when the relative mobilities discussed here were calculated.

Fig. 1 is a log–log plot of m versus molecular weight for all peptides of which details were available with the exception of peptides containing histidine and cysteic acid. The sign of m was ignored. It is seen that a series of straight lines is obtained with a slope of almost exactly $-2/3$. The values of ε assigned to the various lines on this plot are those which the peptides composing them were believed to have on other evidence before this graph was drawn. The slope of the lines and the approximately linear dependence of m on ε when M is held constant correspond to equation (3). It may therefore be that the crude model discussed in connexion with this equation has some elements of truth. Such a plot has a very practical application. The amino-acid compositions of peptides and proteins are obtained after acid hydrolysis sufficiently strong to convert asparagine to aspartic acid and glutamine to glutamic acid respectively. The distinction between these two groups of amino-acids is thus lost although their influence on the biological function of proteins must be very different. Electrophoretic mobility has often been

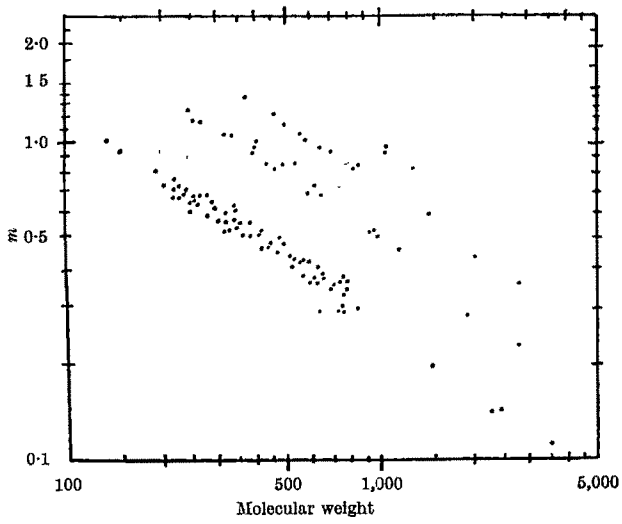

Fig. 1. A logarithmic plot of electrophoretic mobility (at *p*H 6·5, relative to aspartic acid) versus molecular weight for peptides without histidine or cysteic acid. The alignments which are observed correspond (in order of their distance from the molecular weight axis) to $\varepsilon = 1$, 2, 3 and 4

used qualitatively (for example, among many others[6,7]) to distinguish between the two possibilities, but it has been found useful to use Fig. 1 to extend the method to cases where it is necessary to distinguish between, say, a charge excess of one and two. Thus, if a peptide with a composition after hydrolysis of Asp_1Glu_2 has $m = 1{\cdot}05$, the net charge is clearly -2—presumably indicating a terminal carboxyl group, a terminal amino group, two side chain carboxyls free and one amidated. The scatter of the points is such that it may be expected that peptides with ambiguous mobilities may be found, but the lines, at least up to $\varepsilon = \pm 3$, are sufficiently far apart for it to be unlikely that a result could be obtained which would actually be misleading, especially if certain considerations, outlined later, are taken into account.

The plot can also be used either to predict the position of a peptide or in certain circumstances to estimate molecular weight. The spread of points is such as to recommend caution in these cases, especially the latter. While a peptide of composition Asp : Leu : : 1 : 1 and $m = 0{\cdot}65$ is clearly Asp_1Leu_1 and not Asp_2Leu_2 or $Asp_1Asn_1Leu_2$, there are cases where the results are ambiguous. The plot has, however, been found useful as a means of showing up errors in amino-acid analyses and other data.

The reservations referred to relate to the fact that ε is not always integral at *p*H 6·5. The range of *p*K for the imidazoyl side chains of histidine in peptides is about 5·8–7·5 and such peptides are thus unlikely to behave predictably at *p*H 6·5. None is included in Fig. 1, but some idea of the *p*K of this side chain in a particular peptide could presumably be obtained from its position between the lines on the plot.

Suspicions that ε may not be integral are not confined to the case of histidine peptides. The *p*K of the NH_2 group of some peptides may be quite close to 6·5 and it would have been preferable to have collected the data for a slightly lower *p*H, 6·0 for example. Many peptides run poorly at this *p*H as compared with 6·5, however, and the lower *p*H has never been adopted here for the routine preparative work that produced the mobility data. One class of peptides showing a low *p*K effect are certain of those in which basic residues (especially arginine), asparagine, serine and threonine are N-terminal. There appears in these cases to be a difference of at most 10 per cent in the mobility from that which would have been expected. These peptides are included in Fig. 1 and contribute a great deal of the scatter of the points. Anionic peptides of this class have their mobility enhanced and lie above the average line for their nominal net charge, while cationic peptides have their mobility reduced and lie below the line. Nominally neutral peptides of this type have a slight anionic mobility ($m = 0{\cdot}1$). This effect becomes serious at *p*H 7, but Fig. 1 shows that it is still within manageable proportions at *p*H 6·5 for peptides without cysteic acid.

The possession of cysteic acid is observed to cause the peptide to lie nearer the anode, even if this residue is not N-terminal (Fig. 2*a*). This effect is possibly due to the same reason as that already discussed and is seen in Fig. 2*b* to be particularly pronounced in cases where cysteic acid is N-terminal and where there are no other charged side chains. It is possible to devise explanations for the failure to observe such a strong enhancement by N-terminal cysteic acid in the presence of side chain carboxylic groups, but it would be preferable to wait for more data to be collected.

$MetSO_2$ may exert a similar effect to cysteic acid when it is N-terminal. The only peptide in the present collection of data in which this occurs also contains cysteic acid. It shows the enhanced anionic mobility normally charac-

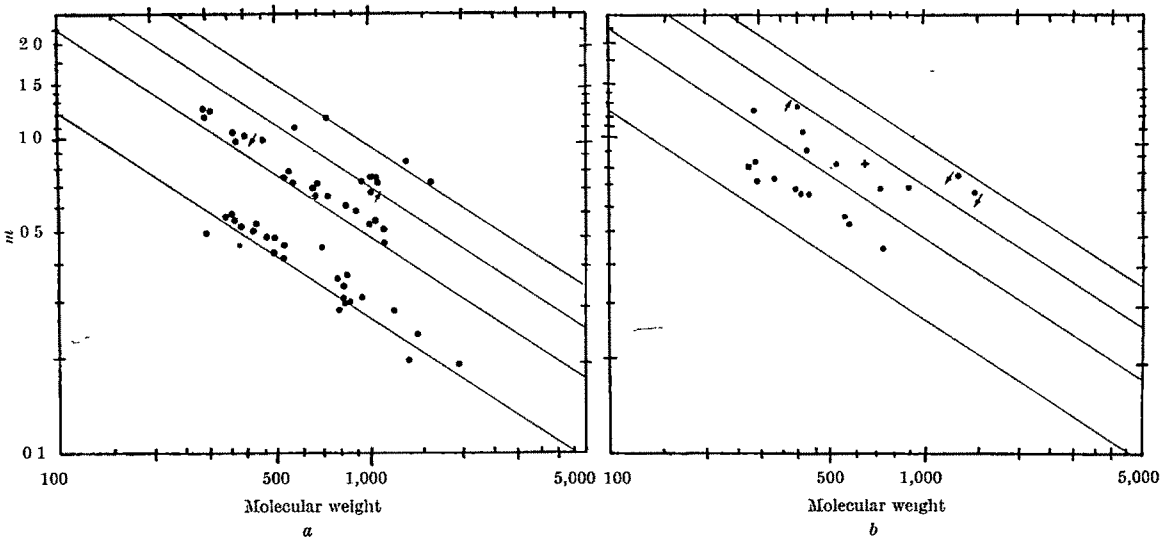

Fig. 2. *a*, A plot, similar to Fig. 1, showing the effect of cysteic acid in positions other than N-terminal (at *p*H 6·5). The diagonal lines indicate the positions of the lines of equal charge in Fig. 1. Certain points have the line on which they should lie indicated by an arrow. *b*, A similar plot showing the effect of cysteic acid in N-terminal positions (at *p*H 6·5). +, 2 cysteic acid residues, one N terminal; ×, 1 cysteic acid residue, $metSO_2$ N-terminal

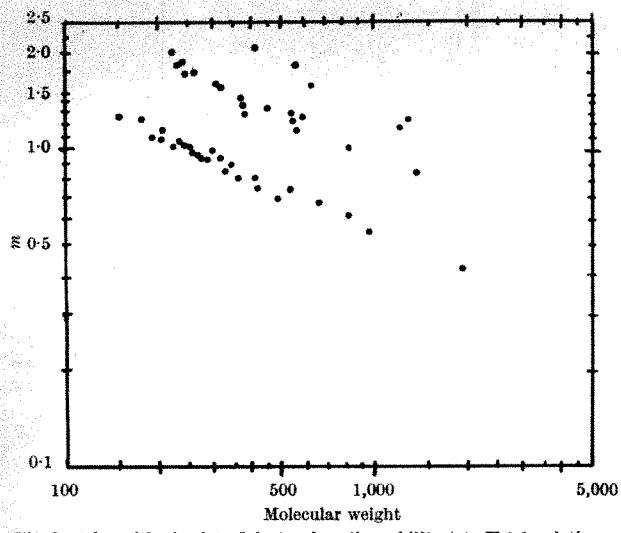

Fig. 3. A logarithmic plot of electrophoretic mobility (at *p*H 1·9, relative to serine) versus molecular weight for peptides without cysteic acid

teristic of N-terminal cysteic acid (Fig. 2*b*). There is some possibility that the sulphone group may suppress the ionization of the terminal carboxyl when $MetSO_2$ is at the carboxyl terminus, as such peptides, when nominally neutral, show in fact a slight cationic mobility at *p*H 6·5. A useful indication that one is dealing with a peptide of which the αNH_2 is suppressed may be obtained by staining on paper with the ninhydrin–cadmium reagent of Barrolier[8]. Such peptides are very frequently those which give a yellow, orange or brown colour as opposed to the normal red. The principal exceptions are peptides with N-terminal glycine which give a yellow colour but have normal *p*Ks, and peptides with basic residues N-terminal which give a red colour even when they have an abnormal *p*K.

A plot of the type described here has also been prepared for use at *p*H 1·9 (Fig. 3). The ionic strength of the 2 per cent formic–8 per cent acetic acid 'buffer' is about 0·01. It is, of course, not possible to distinguish between amidated and non-amidated side chains at this *p*H, but it has been of some use in looking for N-acetyl groups and as a general check on amino-acid analyses of peptides. *p*H 1·9 is dangerously close to the *p*K of some carboxyl groups and points may be found which lie well clear of the lines. One interesting point is that the slope of the lines in this case suggests a state intermediate between that expressed by equation (2) and that by equation (3). The ionic strength may be the determining factor.

Plots have also been made for 'dansyl' peptides[9] and for serine phosphate peptides[10]. It was hoped in the latter case that the plot would assist sequential investigations at the radioactive level, but the influence of the serine phosphate group on the *p*K of other charged groups considerably complicated matters. For such a plot to have been of any use beyond the stage of interpretation of preliminary results, considerably more information on mobilities of peptides in this class would have been required.

In conclusion, although the plot of electrophoretic mobility against molecular weight shown in Fig. 1 has been used extensively by workers in this laboratory, no clear indication of net charge given by it has yet been disproved. The use of this plot for any other purpose but this and the examination of different models of electrophoretic migration is to be viewed with some caution. The more complex circumstances applying to Figs. 2 and 3 also call for care in interpretation, as is the case for plots involving substituted peptide derivatives.

I thank R. F. Ambler, B. S. Hartley, C. Milstein, R. N. Perham, L. F. Smith and A. G. Weeds for supplying me with measurements and other observations on peptide mobility and for useful discussions on their interpretation, Dr. J. I. Harris and Dr. F. Sanger for their interest and encouragement, and the Medical Research Council for a scholarship.

ON SUDAN BLACK POSITIVE MATERIAL IN CONNECTIVE TISSUE

By Dr. A. H. MELCHER

Department of Dental Science, Royal College of Surgeons of England, London, W.C.2

Berenbaum[1,2] has described histological staining of bound substances, possibly lipids, by Sudan black *B* dissolved in acetone. This method sometimes stains reticulin[2,3] and material associated with collagen fibres[2,4]. Calcifying sites can be stained by Sudan black dissolved in 70 per cent alcohol, but only if the positive substance is unmasked before decalcification[5]. Fibroblasts are known to synthesize lipids[6]. These findings suggest that Sudan black positive material may be associated with the formation of hard and soft connective tissues. This possibility was tested in the investigation reported here.

Distal halves of growing tails of 9–11 day *A2G* albino mice were examined. The tails were frozen in solid carbon dioxide immediately after resection. Longitudinal sections of the unfixed, undecalcified tails were cut at about 8μ in a cryostat and thawed on clean slides at room temperature. Sections were post-fixed for 1 h in Baker's formol-calcium and stained by the following methods: in Sudan black *B* (Hopkin and Williams, Batch No. 41143) dissolved in 70 per cent alcohol, either at room temperature for 2 h or by Berenbaum's burnt method[1,2]; in Sudan black *B* dissolved in acetone for 6 h at 60° C[1,2]; in haematoxylin and eosin; by silver impregnation, using the methods of Gömöri for connective tissue fibres and von Kóssa for calcium deposits; and by the periodic acid–Schiff reaction. All sections were dehydrated, cleared in xylene and mounted in Canada balsam except those stained at room temperature in Sudan black *B* in 70 per cent alcohol, which were mounted in glycerin jelly. Although mouse tail contains a wide variety of tissues and is most useful for comparative studies, these observations are restricted to dermis, tendon, annulus fibrosus, endochondral cartilage and developing bone.

Tissues were regarded as being positively stained with Sudan black only if coloured jet black[7]. When stained by Sudan black/acetone (Fig. 1*a*), positively stained

intercellular material was sometimes seen in the 'basement membranes' of the skin, and in the dermis and tendons. By contrast, positive intercellular material was seen in most sections in the annulus fibrosus and in parts of the cartilage, namely the intercellular substance of the basal layers and areas continuous with tendons, and in calcified cartilage identified from sections processed by the von Kóssa method. Newly formed bone of the perichondral collar was also strongly stained in parts. The intercellular substance of maturing cartilage and the fibrous layer of the perichondrium and periosteum were rarely stained. The material coloured by Sudan black/acetone was not stained by either of the Sudan black/alcohol methods.

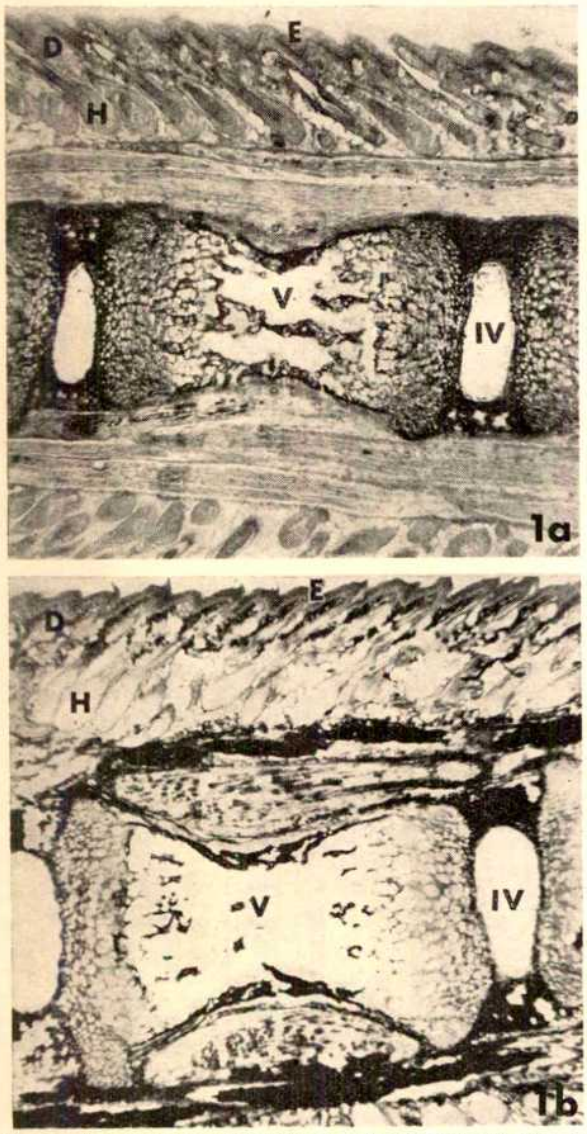

Fig. 1. Longitudinal sections through developing tail of mouse. *a*, Control; *b*, after extraction in chloroform : methanol : hydrochloric acid (2 : 1 : 1/300 v/v/v) at room temperature for 24 h. *E*, Epithelium; *D*, dermis; *H*, hair follicle; *V*, vertebra; *IV*, intervertebral disk. (Sudan black/acetone. ×40)

Collagen fibres were coloured black, red-black or red-brown, or golden by Gömöri's silver impregnation method. There seemed to be some correlation between the location of areas coloured a red-black hue by silver impregnation and black by Sudan black/acetone.

Unfixed cold microtome sections were extracted in a mixture of chloroform : methanol (2 : 1 v/v) or in absolute acetone, either at room temperature or boiling-point, for varying periods up to 48 h. Sections were post-fixed in formol-calcium, stained by the Sudan black methods and compared with non-extracted adjacent sections stained simultaneously. After extraction in these reagents at room temperature, sections stained in Sudan black/acetone showed reduction of "background staining" but increased sudanophilia in some areas, particularly in the annulus fibrosus and the intercellular substance of cartilage described above. These areas were not stained by the Sudan black/alcohol methods. Little or no material in dermis and tendon was stained by Sudan black/acetone after 24 h extraction in boiling chloroform : methanol or acetone, and the positive material in the annulus fibrosus was gradually removed. However, sudanophilic material in the intercellular substance of the basal attachment and calcified areas of the cartilage, but not usually of the bone of the perichondral collar, was increased. Forty-eight hours' extraction rarely removed all this stainable material from the calcified tissues, but frequently removed it from uncalcified cartilage.

It is known that some compound lipids can be isolated from neural tissue only by extraction in chloroform : methanol containing hydrochloric acid (see ref. 8). To determine whether further Sudan black positive material in connective tissue could so be disclosed, additional unfixed sections were extracted in chloroform : methanol : concentrated hydrochloric acid (2 :1 : 1/300 v/v/v). Room temperature extraction resulted in intense staining by Sudan black/acetone (Fig. 1*b*), but not by Sudan black/alcohol, of material associated with both hard and soft connective tissues. Strongly sudanophilic material was seen to be associated with the "basement membranes" of the skin, the connective tissue fibres of dermis, tendon, annulus fibrosus, perichondrium and periosteum, intercellular substance of basal and attachment areas of endochondral cartilage, calcifying cartilage and bone of endochondral collar, but only rarely with the intercellular substance of maturing cartilage. Staining of areas containing sudanophilic material in unextracted sections was intensified by extraction. Maximum staining was obtained after room temperature extraction for 1–48 h, the time varying between specimens. Thereafter, no noticeable increase in intensity occurred, and eventually there was gradual disappearance of stained material. Staining of calcified cartilage and bone of perichondral collar was more persistent but was prevented by extraction for 130 hours, which often caused hydrolysis of tissues. Extraction in boiling reagent removed all stainable material, sometimes within 24 h.

Some sections containing large quantities of material positively stained after extraction in chloroform : methanol : hydrochloric acid were demounted by soaking in xylene, and then rinsed in absolute alcohol. Subsequent transfer to chloroform : methanol (2 : 1 v/v) at room temperature removed the stain from soft connective tissue in 1 min or less, but stained material was still present in calcified cartilage and bone after 1 h. Attempts to restain the sections in Sudan black/acetone were largely unsuccessful. Periodic acid–Schiff positive material in sections extracted by the methods already described did not behave like the Sudan black-positive material.

In a further experiment, healthy skin and 8 mm punch wounds healing up to 25 days in the dorso-lateral skin of three *Macaca irus* monkeys aged about 5·5 years were examined by the methods already described. The monkeys had been fed a high carbohydrate-containing cariogenic diet for at least 4·5 years. Material, positively stained by Sudan black/acetone but not by the Sudan black/alcohol methods, and extractable by chloroform : methanol and by acetone, was found in healthy excised skin. It is not yet known whether this finding was in any way related to the animals' diet. This material seemed to be located in areas corresponding to those coloured red-black in adjacent sections impregnated by Gömöri's

silver method. Extraction at room temperature in chloroform : methanol : hydrochloric acid markedly increased the quantity of Sudan black/acetone stainable material associated with the collagen fibres.

Sudan black/acetone stained material was also found in relation to unextracted collagen fibres laid down in the healing wounds, again in areas apparently corresponding with those of a red-black hue in adjacent silver impregnated sections. The amount of material in the healing connective tissue stained by Sudan black/acetone after extraction in chloroform : methanol : hydrochloric acid at room temperature appeared to be related to the quantity of mature collagen fibres present in the wound. The intercellular substance of the connective tissue of the adjacent skin was always more heavily stained than the developing connective tissue of the wounds.

The material stained by Sudan black/acetone in unextracted sections in the foregoing experiments was never stained by either of the Sudan black/alcohol methods, but it could be extracted from soft connective tissues by acetone or chloroform : methanol. These findings suggest that it comprised bound lipids. These probably are not glycolipids, and their identification must await microchemical analysis.

Sudan black/acetone-stained material was seen in calcified cartilage, the sudanophilia of which has been established by Irving[5] using a different technique, and also in mineralized bone. However, the solubility of these substances is different from those in soft connective tissue, and this investigation has contributed little to their identification.

Bound lipids can be unmasked *in vitro* to histochemical reactions (see refs. 2 and 9). Some extracellular bound lipid-like substances in the connective tissues examined here have been unmasked and stained by Sudan black/acetone alone; others have been unmasked to Sudan black/acetone only after extraction, particularly by chloroform : methanol : hydrochloric acid. In this connexion, it is of interest that some protein-bound phospholipids can be extracted from brain partly by acetone and wholly by acidified chloroform : methanol[8]. Processes effecting the extraction of bound lipids appear to disrupt molecular attachments and relationships[8,10], thus possibly making the lipids accessible to staining reagents[11], although prolonged extraction removes them entirely. The ease with which sudanophilic material can be unmasked and extracted probably reflects its degree of binding in the tissues.

The use of extraction procedures indicated the presence of far greater quantities of sudanophilic material in these connective tissues than has hitherto been demonstrated. There was some evidence that in soft connective tissue the amount of material unmasked only by chloroform : methanol : hydrochloric acid increased with maturation. The sudanophilia of unextracted sections of soft connective tissues was variable, and it is suggested that this reflects "*in vivo* unmasking" of bound lipid-like substances which may represent a stage in their incorporation into developing connective tissue and perhaps in their dissociation from resorbing connective tissue. These possibilities are now being investigated.

This investigation was carried out during the tenure of a Leverhulme research fellowship. I thank Dr. G. H. Sloane-Stanley and Dr. J. E. Eastoe for helpful discussion of the problem.

ISOLATION OF A CHONDROITIN SULPHATE PROTEIN COMPLEX FROM BOVINE INTERVERTEBRAL DISKS

By Dr. D. A. LOWTHER and ELSMAREE BAXTER

Department of Biochemistry, Monash University, Clayton, Victoria

The intervertebral disk is a flattened cylindrical structure consisting of two distinct regions, an outer fibrocartilaginous ring or annulus and an inner gelatinous portion, the nucleus pulposus[1]. Several workers have shown the presence of acid mucopolysaccharides in both the nucleus and annulus in stained histological sections[2,3]; these have been isolated and identified as keratosulphate[4] and chondroitin-6-sulphate[5]. Marked changes in the proportions of these polysaccharides and their total amount in relation to the collagen content of the disk have been noted during ageing[6].

In most of these investigations the mucopolysaccharides were isolated by methods involving the destruction of tissue protein. However, Malawista and Schubert[7] showed that a more complex molecule containing mucopolysaccharide covalently bound to protein could be extracted from bovine nasal cartilage by homogenizing this tissue in water at 0° C. Further examination of the extracted molecule showed the presence of both chondroitin sulphate and keratosulphate bound to protein[8,9] and it has been suggested that both mucopolysaccharides are bound to the same protein[8].

Evidence for the presence of a similar mucopolysaccharide protein complex in bovine intervertebral disk is presented in this article.

Ninety grams of fresh bovine intervertebral disks were minced in a power mincer at 0° C and then homogenized in 1,500 ml. of distilled water as described by Malawista and Schubert[7]. The procedure was repeated until the nitrogen and hexosamine in the final extract were less than 5 per cent of that in the first extract. The residue was then further extracted with molar sodium chloride in a similar manner. The pooled extracts were dialysed and the content of acid mucopolysaccharide determined in a portion of the extracts by proteolytic digestion with papain and isolation of the mucopolysaccharides as described by Scott[10]. It was found that 87 per cent of the acid mucopolysaccharide in the tissue could be extracted under these conditions as determined by the hexosamine content of the quaternary ammonium precipitated material.

Treatment of the dialysed extracts from disks with the quaternary ammonium salt, cetyl trimethyl ammonium bromide (CTAB), resulted in the precipitation of a crude mucopolysaccharide protein complex. After washing

E., and Harrison, J. S., *Biochem. J.*, **50**, 298 (1952). (*f*) Dodgson, K. S., and Price, R. G., *Biochem. J.*, **84**, 106 (1962).

the precipitate with water, the quaternary ammonium ion was removed by shaking the precipitate with a saturated solution of potassium thiocyanate in ethyl alcohol at room temperature. This procedure was repeated three times and the product finally dissolved in distilled water. High-speed centrifugation for 2 h at 45,000 r.p.m. (Spinco model *L* No. 50 head) resulted in the separation of a small amount of gel similar to that found in preparations from bovine nasal cartilage[11].

Further purification of the dissolved mucopolysaccharide protein complex was achieved by passing the solution through a column of 'Ecteola' ion exchange resin in the chloride form. This treatment removed some protein, but 75 per cent of the mucopolysaccharide protein complex was present in the effluent. The eluate was dialysed and dried from the frozen state. The low capacity of the 'Ecteola' resin for the mucopolysaccharide protein complex makes this a useful method for separating the complex from free acid mucopolysaccharide. The capacity of the resin for mucopolysaccharide when isolated from the mucopolysaccharide protein complex is at least sixty times greater than that for the parent complex.

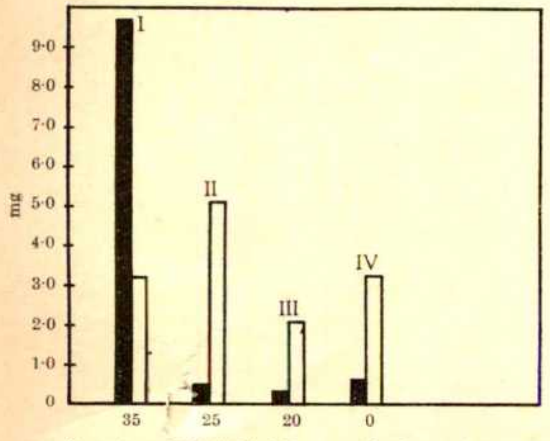

Fig. 1. Elution of keratosulphate (■) and chondroitin sulphate (□) from cellulose column with decreasing concentrations of ethanol

An analysis of the isolated mucopolysaccharide protein is shown in Table 1. The molar equivalence of galactosamine and uronic acid (1) and glucosamine and hexose (2) suggested the presence of both chondroitin sulphate and keratosulphate. This was confirmed by digestion with papain and the separation of the two mucopolysaccharides on a cellulose column (Fig. 1) as described by Gardell[12]. The protein content was similar to that found in the complex isolated from bovine nasal cartilage, but the ratio of keratosulphate to chondroitin sulphate was considerably higher (Table 1).

An examination of the sedimentation behaviour in the Spinco model *E* analytical ultracentrifuge showed that the preparation was apparently homogeneous (Fig. 2). A small quantity of a faster component was also present, but this could not account for more than 5 per cent of the dry weight of the material. Further purification did not remove it. The molecule remained at the origin when electrophoresis was carried out on starch or acrylamide gels, but moved as a single symmetrical peak in free boundary electrophoresis, at *p*H 5·0 in an acetate buffer, and at *p*H 6·4 in a phosphate buffer ($I = 0{\cdot}2$) (see Fig. 3).

A preliminary examination of the protein component showed it to contain little or no hydroxyproline, which

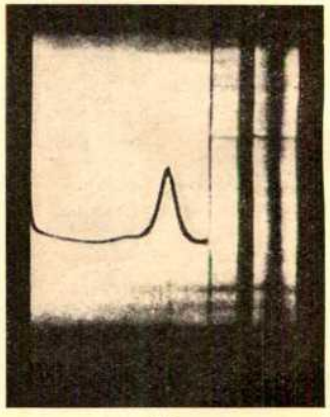

Fig. 2. Sedimentation velocity pattern of mucopolysaccharide protein complex. Sedimentation in 0·005 M phosphate buffer *p*H 7·8 containing 0·15 M potassium chloride. Mucopolysaccharide concentration 0·4 g/100 ml.

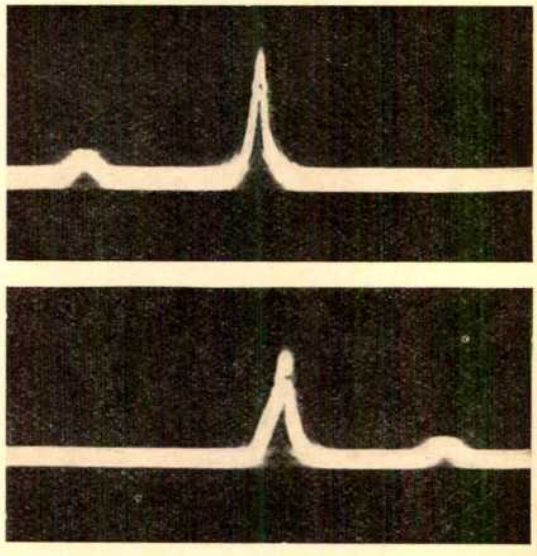

Fig. 3. Electrophoretic pattern of mucopolysaccharide protein complex *p*H 6·5 in phosphate buffer ($I = 0{\cdot}2$). Photograph taken after 60 min at a potential gradient of 6·1 V/cm². *A*, Ascending limb; *B*, descending limb

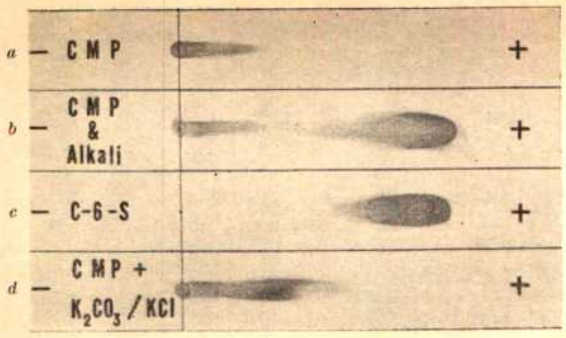

Fig. 4. Paper electrophoresis of the mucopolysaccharide protein complex and the derived mucopolysaccharides. 5 μl. spots containing 30–40 μg of preparation were applied to strips of Whatman 3*MM* paper (2·5 × 34 cm). Electrophoresis was carried out in an Eel apparatus in 0·1 M acetate buffer *p*H 5·0, containing 6 M urea, for 5 h at 4 V/cm. The strips were stained with aqueous toluidine blue. *a*, Untreated polysaccharide protein complex; *b*, alkali treated polysaccharide protein complex; *c*, papain digested polysaccharide protein complex; *d*, polysaccharide protein complex treated with potassium carbonate/potassium chloride mixtures. Mixtures of polysaccharide protein complex and polysaccharide can be completely resolved under these conditions

indicated that collagen was absent, and it did not give any precipitation lines with antibovine serum preparations when examined by the method devised by Ouchterlony[13]. Thus the protein does not seem to be either a serum component or collagen.

Muir[14] showed that the polysaccharide protein complex from pig tracheal cartilage was labile to alkali releasing free polysaccharide. Treatment of the intervertebral disk preparation with 0·5 N sodium hydroxide released material which on electrophoresis had the same mobility as chondroitin sulphate (Fig. 4). This alkali lability would account for the suggestion by Bernardi *et al.*[15] that material extracted from human nucleus pulposus with 1 per cent potassium carbonate containing 30 per cent potassium chloride (*p*H 10·5) contained a mixture of a mucoprotein and mucopolysaccharide. Treatment of purified mucopolysaccharide protein complex from bovine disks with the potassium carbonate/potassium chloride mixture for 60 h at room temperature resulted in a partial degradation as shown in Fig. 4.

We could not find any evidence for the presence of free mucopolysaccharide in our extracted material, thus 87 per cent of the total mucopolysaccharide in the tissue was extracted and shown to be present in a complex molecule containing chondroitin sulphate, keratosulphate and protein.

This investigation was supported by a grant from the Australian National Health and Medical Research Council. The free boundary electrophoresis was kindly performed by Dr. M. Gillespie of the C.S.I.R.O. Wool Research Division on a Tiselius apparatus, using Schlieren optics. The Ouchterlony diffusion test was undertaken by Dr. P. Ironside of the Department of Pathology, Monash University.

DIMINUTION IN APPARENT ORGANIC PEROXIDE ("PRO-BLUE") IN MICE GIVEN AN ORAL CONTRACEPTIVE

By V. J. HORGAN and J. St. L. PHILFOT
Medical Research Council Radiobiological Research Unit, Harwell, Didcot, Berkshire

THE term "apparent organic peroxide" used here refers to what we have called "pro-blue"[1,2], an unknown substance or group of substances extractable by *n*-butanol from biological material and capable of oxidizing leuco-brilliant cresyl blue in the absence of air. We suspect, without proof, that pro-blue usually consists of hydroperoxides of unsaturated lipids formed by the chain reaction known as autoxidation. We have shown that pro-blue is increased not only by irradiation[2,3] but by alarm[4], and that some of the increase is in the fat surrounding sex organs[2] (ovaries in female, epididymis in male). The fact that deficiency of the natural antioxidant tocopherol causes sterility suggests that sterility may result from the autoxidation of ovarian or epididymal fat, even though tocopherol-deficient animals do not show an overall increase of pro-blue[5]. If this conjecture were true, the sterilizing effect of an unsuitable social environment in some animals could be a result of neurogenic autoxidation induced by frequent mild alarm. Neurogenic autoxidation could also explain the allegedly high incidence of arterial disease (including thrombosis) in business executives and others exposed to mental stress, as arterial disease is widely thought to be related in some unknown way to deficiency of unsaturated lipids, which could result (in addition to the production of toxic peroxides) from neurogenic autoxidation. Thus, neurogenic autoxidation may provide a link between neurogenic sterility and neurogenic arterial disease.

Pharmacogenic sterility has become of great social importance with the advent of progestin-like oral contraceptives. The suggestion that they may increase the incidence of thrombosis has been discussed[6], but evidence for it is weak or non-existent. Nevertheless it suggests, by analogy, the possible existence of pharmacogenic autoxidation as a common cause of sterility and thrombosis as in the partly hypothetical neurogenic case. A pharmacogenic rise in pro-blue is easily looked for in mice by our standard procedure, and we have done so.

The experiments were done with albino hairless mice (*hr hr*), individuals being selected at random and treated or not in random order. The contraceptives, in powder form (1·5 mg), were mixed with a paste of 'Horlicks Malted Milk' in water and given daily for 2 days to each experimental mouse. The control mice were given a similar amount of 'Horlicks' without the contraceptives. The precautions against alarm were as described in previous papers[1,3,4]. The peroxide estimation was as already described[2] with the following modifications.

Cadmium filings were made by filing a cadmium bar with a rough rasp. The filings were washed consecutively with dilute acetic acid, distilled water and acetone, and then dried in air. Copper powder was sieved and the

The observed difference in means would occur by chance less than 1 in 30 times and is, therefore, significant.

fraction between 40 and 80 mesh per in. was used. The powder was washed consecutively with acetic acid, acetate buffer (*p*H 5), distilled water and acetone, and then dried in air. An 8×10^{-3} M solution of brilliant cresyl blue (molecular weight of hydrochloride, 245) was made in 0·5 M 2 : 6 lutidine plus 0·25 M acetic acid, all in *n*-butanol. This was diluted with 9 volumes of *n*-butanol for use. A 5×10^{-3} M solution of A.R. hydrated cupric chloride was made in 0·1 M lithium bromide plus 0·02 M lithium acetate, all in *n*-butanol.

In the first experiment, the results of which are shown in Table 1, two contraceptives were tested, 'Enavid' and 'Ovulen' (kindly supplied by G. D. Searle and Co., Ltd.). Six control and six experimental mice, 6 weeks old, were used with each.

A further experiment (Table 2) with 12 control and 12 experimental mice was done using 'Ovulen' only. The mice were 13 weeks old and therefore fully mature. 'Ovulen' in powder form (1·5 mg) was given daily for 5 days to each experimental mouse. A vaginal lave was taken from each mouse immediately after it was killed with nitrogen, to determine the phase of oestrus.

For the experiment in Table 3, mice 13 weeks old were used without contraceptives. After being killed with nitrogen the phase of oestrus of each mouse was determined. When six mice in any particular phase had been used, further mice found in that phase were rejected so that the work of pro-blue estimation could be concentrated where it was most needed.

Table 3. MICROMOLES OF PEROXIDE ("PRO-BLUE") PER MOUSE

	Pro-oestrus	Oestrus	Metoestrus	Means of rows
	2·16	4·33	6·33	4·27
	1·50	3·67	4·66	3·28
	8·33	8·16	6·50	7·66
	6·66	7·33	7·33	7·11

	7·33	10·99	8·33	8·88
Means of columns	5·47	6·94	6·94	

The result in Table 2, which confirms the preliminary result in Table 1, has revealed a new phenomenon, the reverse of what was expected, in that the contraceptive 'Ovulen' has produced a statistically significant diminution in total pro-blue, and the preliminary results (Table 1) suggest that 'Enavid' may behave similarly. The observed differences in means shown in Table 1 would occur by chance about 1 in 6 and 1 in 4 times respectively and are therefore not significant. The pooled differences of means ('Ovulen' plus 'Enavid') are also not significant, but the pooled means of differences between treated and untreated mice examined at approximately the same time are significant ($P < 0{\cdot}02$), which suggests that a slow drift with time accounts for some of the large variance. The difference of means in Table 2 is significant with or without elimination of time.

We tried to explain the diminution in pro-blue by looking without success for an antioxidant action of 'Ovulen' *in vitro*. We also thought that the pro-blue level might vary with the oestrus cycle which might be blocked by 'Ovulen' in a low-peroxide phase. Actually, 'Ovulen' was found (Table 2) to block in the metoestrus phase (an unexpected and possibly new observation), but the mean pro-blue in metoestrus in control mice was no lower than in oestrus though a statistically insignificant fall ($P = 0{\cdot}33$) was observed in pro-oestrus (Table 3). In Table 3, the means of rows, which are in chronological order, show an obvious effect of time. This was found by analysis of variance to be significant ($P < 0{\cdot}01$); but even when it was allowed for, the pro-oestrus column was not significantly different from the other two.

The chief result of the present work is thus the discovery of an unexplained new phenomenon, low pro-blue in 'Ovulen'-treated mice. The explanation, when it comes, may throw some light on the means by which ovulation is regulated both naturally and artificially.

5-HYDROXYTRYPTOPHAN UPTAKE BY DOG THYROID 'C' CELLS, AND ITS POSSIBLE SIGNIFICANCE IN POLYPEPTIDE HORMONE PRODUCTION

By PROF. A. G. E. PEARSE

Department of Histochemistry, Postgraduate Medical School of London, Ducane Road, London, W.12

THE *C* cells of the dog thyroid have been shown to be identical with the argyrophil parafollicular cells described in that animal by Nonidez[1,2]. As indicated in earlier papers[2,3], these cells are sensitive to physiological changes in serum calcium-levels and they respond to high calcium-levels, of short duration, by discharging their contents. It has been postulated that the secretion product of the *C* cells is calcitonin (thyrocalcitonin)—the calcium-regulating hormone in the serum[2,3].

Evidence was recently provided by Hargis *et al.*[4], who used an immunofluorescent technique on pig thyroid, that thyrocalcitonin "must be synthesized or stored in the same cells that elaborate thyroglobulin". These are indisputably the acinar ('*A*') cells. Notwithstanding,

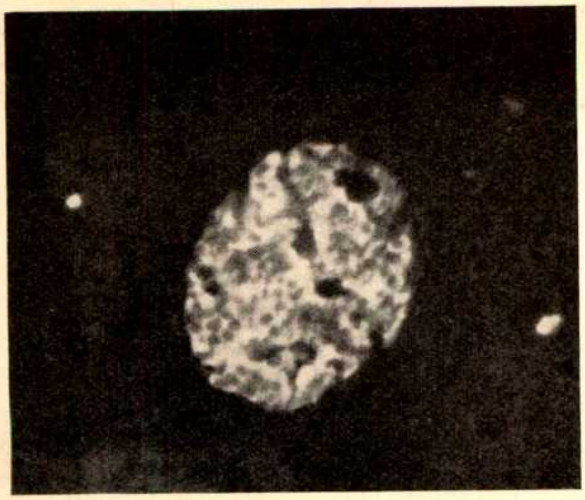

Fig. 1. Dog pancreas exhibiting 5-HT fluorescence in the β-cells after administration of 5-HTP. (× 420)

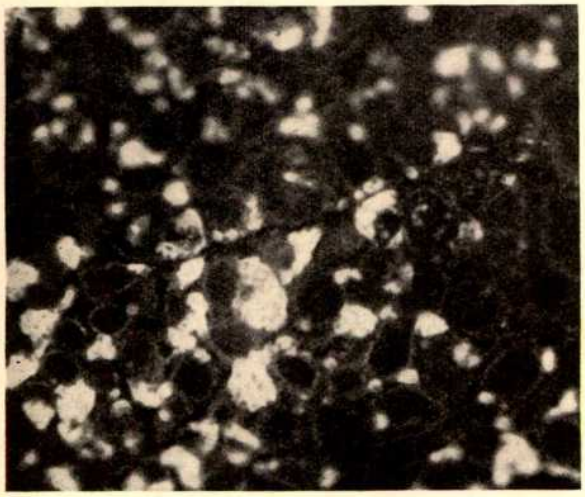

Fig. 2. Dog thyroid showing 5-HT fluorescence in the *C* cells after administration of 5-HTP. (× 180)

Bussolati and Pearse[5] have reported that when it is not subjected to the diffusing effect of "fixation" in solvent (acetone), calcitonin, in the pig thyroid, can be shown by immunofluorescence to be present in the *C* cells and possibly in the vascular pericytes. As yet it has not been proved that this indicates synthesis of calcitonin by the *C* cells as well as storage.

An interesting property of the *C* cells is their ability to concentrate injected 5-hydroxytryptophan (5-HTP) and, possibly, to convert this to 5-hydroxytryptamine (5-HT). Both can readily be shown by the fluorescent amine technique[6,7]. Puppies and young dogs were given 5-HTP (25 mg/kg) intraperitoneally and killed after 4–6 h. Control animals of similar weight and sex were also examined. Selected tissues were freeze-dried for 6–8 h at −40° C in a thermo-electric dryer[8]. They were then treated with formaldehyde vapour at 50° C for 1 h (28 per cent humidity). As indicated by Falck and Hellman[9] for the pancreas of the guinea-pig, specific 5-HT fluorescence was found in the β-cells of the islets. In the control dogs, however, it was only faintly visible and in a small proportion of the cells. After 5-HTP injection, the 5-HT fluorescence of the β-cells in the islets was greatly increased (Fig. 1).

Fig. 3. As Fig. 2. Characteristic autofluorescence in Golgi region of the *A* cells and induced 5-HT fluorescence of the *C* cells. (× 510)

A slight augmentation of 5-HT fluorescence was also observed in the anterior pituitary corticotrophs and in the melanotrophs of the pars intermedia. As shown by Pearse and MacGregor[10] for pig, rat and man, the normal corticotrophs have a moderately intense 5-HT fluorescence after freeze-drying and formaldehyde vapour treatment. The melanotrophs of pig, rat and dog were found to be positive; those of rabbit and guinea-pig were negative.

Of all the dog tissues examined, however, the strongest new 5-HT or 5-HTP fluorescence was shown by the parafollicular *C*-cells (Figs. 2 and 3). In all species so far examined (rat, rabbit, guinea-pig, dog, man), these cells have shown

Table 1. COMMON CYTOCHEMICAL PROPERTIES OF 5-HTP AND 5-HT CELLS

Organ and cell	Supposed origin	Product and mol. wt.	High 5-HTP uptake	Normal 5-HT content	High α-GPD* content	High esterase (E) or cholinesterase (ChE)

* Mitochondrial α-glycerophosphate dehydrogenase.

no specific 5-HT fluorescence in normal animals. The fine granular (orange) fluorescence seen in the acinar cells (Fig. 3) is invariably present in the normal dog thyroid. It is possibly associated with the formation of lysosomes in the Golgi region of the *A* cells. The colour of this fluorescence, and the fact that it does not fade, distinguishes it from that of 5-HT.

Uptake of 5-HTP by the parafollicular cells was first noted, in the mouse, by Ritzen *et al.*[11], who used an autoradiographic technique with ^{3}H-5-HTP. They found that the latter was initially accumulated "in the exocrine pancreas and other organs characterized by a rapid protein synthesis". After 4 h the pattern of storage closely approximated the "amine pattern" found after injection of ^{14}C-5-HT. Here storage was particularly in the adrenal medulla, the thyroid, the islets of Langerhans, bone marrow, spleen, lung, mast cells and enterochromaffin cells.

If one considers the principal cell types which are now seen to be involved in 5-HTP uptake and conversion (adrenal medullary cells, enterochromaffin cells, mast cells, pituitary corticotrophs and melanotrophs, pancreatic islet β-cells, thyroid *C* cells) it may be significant that in four out of seven cases the apparent principal product is a polypeptide hormone. It has already been suggested[2] that cells producing polypeptide hormones may have common cytochemical and electron microscopic properties. Cytochemical features common to the seven cell types are given in Table 1. No account is taken of species differences, which are often considerable, but most items refer to dog, rat, rabbit, or pig. The four cells of supposed entodermal origin fall into one group and the non-entodermal representatives into a second group. This division is not absolutely clear, however, as the enterochromaffin cells are now usually regarded as entodermal derivatives and it is possible that the thyroid *C* cells are non-entodermal (neuroectodermal). In some species these cells are not only found in the thyroid but also in other regions (parathyroid, thyroglossal duct), which suggests a common non-thyroid, non-parathyroid origin. Of two possibilities (ultimobranchial bodies, neural crest) the first is the more likely. A neural crest origin for the pituitary corticotroph and for the pancreatic islet β-cell also seems basically unlikely.

Where it is present, a high mitochondrial α-glycerophosphate dehydrogenase may indicate high phospholipid synthesis and high ChE (pseudocholinesterase) may have a similar implication. (In one animal, the rabbit, the *C*-cell enzyme reacts as a specific acetylcholinesterase.) The common denominator in the four polypeptide-producing cells may be the lipid-bound vesicles, averaging 2000 Å in diameter, which can be observed with an electron microscope. The specific product of the cells is apparently stored in the vesicles in a form available for immediate secretion. If in the latter process the vesicles are consumed, then high phospholipid synthesis will be required.

Whatever their precise origin, the details presented here suggest that pituitary corticotrophs, pituitary melanotrophs, pancreatic islet β-cells and thyroid *C*-cells develop from a common ancestral type. Their uptake of 5-HTP and its conversion to 5-HT may then be a demonstration of a no longer utilized ancestral function. It is not easy to postulate the use of 5-HTP as a tryptophan precursor for peptide synthesis. If this were the case the pancreatic islet α-cells (glucagon), with their high need for tryptophan would surely manifest high uptake. A possible function of 5-HT might be in connexion with capillary permeability and facilitation of the passage of the polypeptide product through the vessel wall.

Clearly, at the present time, no unifying concept is possible, but re-investigation of the developmental embryology of the four cell types, by cytochemical methods, is certainly indicated.

EXTRUSION OF ATPase ACTIVITY FROM PINOCYTOTIC VESICLES OF ABUTTING ENDOTHELIUM AND SMOOTH MUSCLE TO THE INTERNAL ELASTIC MEMBRANE OF THE MAJOR ARTERIAL CIRCLE OF THE IRIS OF RABBITS

By DR. CHARLES A. SANTOS-BUCH*

Department of Pathology, Emory University, School of Medicine, Atlanta, Georgia

IT is probable that Freidrick Arnold was the first to describe the circular venosus iridis in man[1]. Careful anatomical dissections later showed that this vascular structure was the larger of two arterial circuits formed by the anastomoses of the long posterior ciliary arteries and perforating branches of the anterior ciliary arteries. The long posterior and anterior ciliary arteries are branches of the ophthalmic artery. Light microscopy has shown that the major circuit is lined by a single row of flattened endothelial cells; the internal elastic lamina contains sparse numbers of fibrils, the media consists only of two rows of smooth muscle cells with meandering fibres between the contractile elements, the external elastic membrane is absent, and there are only a few fibroblasts and loose collagen fibres in the adventitia. The major arterial circuit of the iris, therefore, is structurally very similar to equally sized arteries of the brain. The iris, like the brain, is largely derived from ectoderm, for even the sphincter muscles, like the erector pili muscles of the skin, have that embryonic origin[2]. The iris, too, is a limiting organ to the flux of the humour of the anterior chamber of the eye and, in disorders of lipid metabolism, it is the site of a lesion known as arcus senilis. These considerations have suggested a high degree of metabolic activity in the iris.

Accordingly, a study of the cytochemical localization of ATPase activity in the major arterial circuit of the iris of albino rabbits was undertaken. The major arterial circuit is readily visualized in the white iris of albino

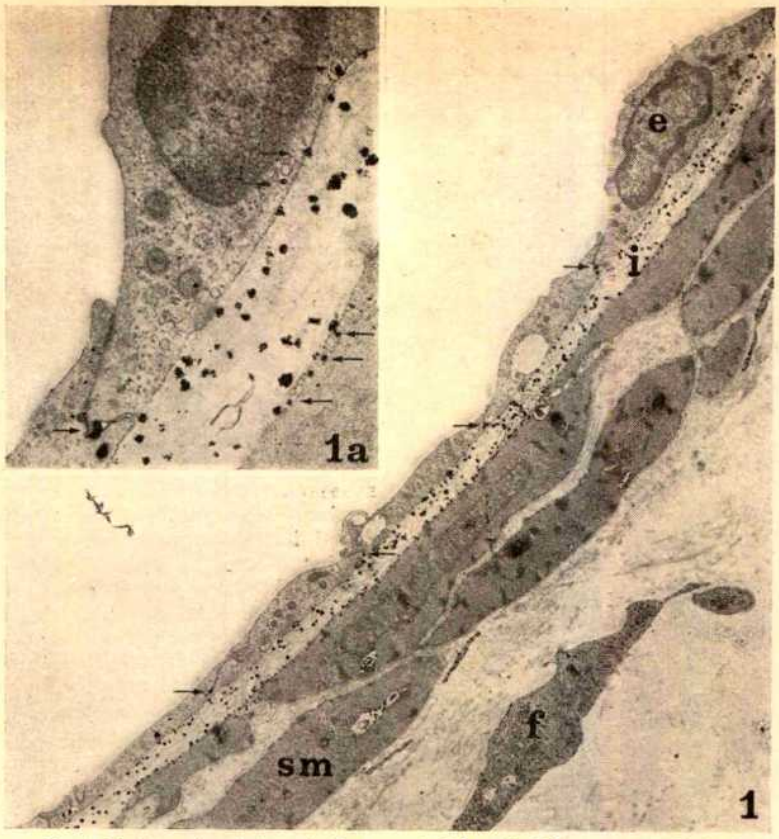

Fig. 1. Electron microphotograph of a segment of the wall of the major arterial circuit of the iris of a normal rabbit which was incubated in $1{\cdot}25 \times 10^{-3}$ M ATP for 0·5 h at room temperature (see text). Note the accumulation of reaction product (lead phosphate) at endothelial junctions (arrows) and the greater number in close proximity to the plasma membranes of the endothelium (*e*) and smooth muscle layer (*sm*) bordering the internal elastic lamina (*i*). Note that no reaction product is present in the luminal pinocytotic vesicles of the endothelium or in the pinocytotic vesicles of the smooth muscle that are not in close proximity to the internal elastic lamina. The cytoplasm of an adventitia fibroblast (*f*) contains minute granules of reaction product. (× *c.* 6,000)

Fig. 1*a*. Higher magnification of the upper right-hand corner of Fig. 1. Note reaction product deep within pinocytotic vesicles of the endothelial and smooth muscle membranes abutting the internal elastic lamina. In some instances reaction product partly extrudes into the interfibrillary spaces of the internal elastic lamina (arrows). Note the accumulation of reaction product beneath the desmosome at the endothelial junction in the lower left-hand corner of the photograph. (× *c.* 25,000)

rabbits. The irises were fixed by isobaric perfusion of each of the common carotid arteries of several rabbits with 300 ml. of cold 1·5 per cent steam-distilled glutaraldehyde buffered with 0·025 M *s*-collidine–hydrochloric acid at *p*H 7·4 for a period of 30 min. The fixative contained 0·015 M magnesium chloride and 0·015 M calcium chloride. Some of the cations were probably chelated by partially charged aldehydic groups and iso-osmolarity was achieved and controlled with complementary amounts of sucrose. The osmolar values of the fixative are given in Table 1. After perfusion, the irises were removed and narrow longitudinal blocks containing segments of the arterial circuit were washed three times for 4–6 h in the cold in iso-osmolar sucrose with 0·03 M magnesium chloride in 0·025 M *s*-collidine–hydrochloric acid buffer (*p*H 7·4). Cross-sections of the segments of the arterial circuit were then cut about 50μ thick by means of a McIlwain's tissue chopper[3] and placed in the test substrates for 30 min at room temperature. The incubating media were similar to those used by Marchesi and Barrnett[4] except that *s*-collidine–hydrochloric acid buffer was used throughout. The filtered substrate solutions were saturated with lead nitrate as the trapping agent and contained $1{\cdot}25 \times 10^{-3}$ M ATP (Nutritional Biochemical Corporation), 0·01 M magnesium chloride, and 0·08 M *s*-collidine–hydrochloric acid buffer at *p*H 7·0. Control studies included incubation of arterial segments in separate media each with equimolar concentrations of (*a*) adenylic acid (AMP) and (*b*) β-glycerophosphate as well as in (*c*) a solution without substrate. The tissues were then washed with buffered sucrose for 15 min and fixed for 0·5 h in the cold in 1 per cent osmic tetroxide in veronal buffer[4]. The tissues were then dehydrated in graded alcohols and embedded in 'Maraglas'[5]. The cross-sections of the arteries were properly oriented in the capsules by careful microdissection in partly polymerized plastic. Sections were made by means of a Porter–Blum microtome with a diamond knife, mounted on 200-mesh copper grids, and stained with lead hydroxide. Electron-microphotographs were taken with an R.C.A. *EMU 3G* electron microscope operating at 50 kV.

None of the irises incubated in control media showed any reaction product when examined under the electron microscope. The substructure of the components of the

Table 1. OSMOLAR VALUES OF FIXATIVE

0·025 M *s*-collidine-hydrochloric acid buffer (*p*H 7·4)	50	
0·015 M magnesium chloride	45	
0·015 M calcium chloride	45	275†
1·5 per cent glutaraldehyde	163*	
0·035 M sucrose	35	35
	338	310

* This osmolarity was used in all preparations of fixative.
† This value was determined separately. About 28 mosm/l. were "lost" possibly by chelation of cations by partially charged aldehydic groups.

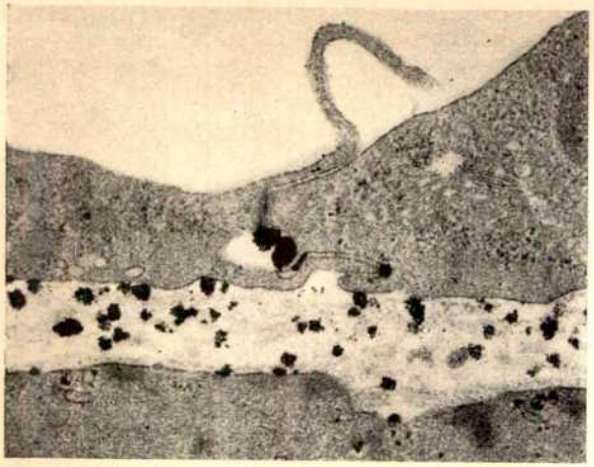

Fig. 2. Granules of electron-dense reaction product are present in cul-de-sac beneath a marginal fold and desmosome of two adjoining endothelial cells. Reaction product is also present in interstices of the internal elastic lamina and abutting pinocytotic vesicles. Tissue incubated in ATP media (see text). (× *c.* 31,500)

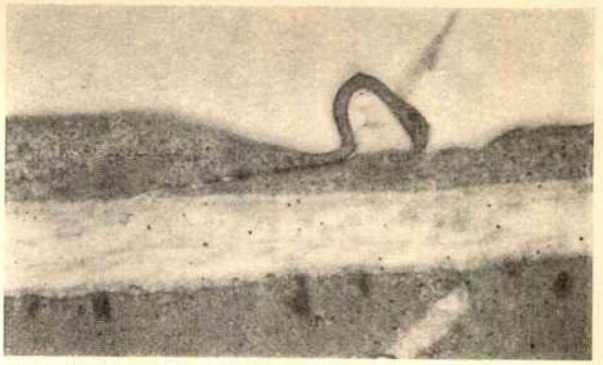

Fig. 3. Cul-de-sac beneath marginal fold and desmosome as well as the area of the internal elastic membrane and pinocytotic vesicles of abutting plasma membranes do not show reaction product in artery after incubation in media without ATP substrate. (× *c.* 24,900)

iris was well preserved. The arterial circuit was lined by sometimes overlapping endothelial cells that were interconnected by desmosomes. The endothelium was closely applied to the internal elastic lamina which was formed by a limited number of elastic fibres and contained numerous interfibrillary spaces. The subjacent media was formed by two rows of smooth muscle cells which were not closely applied to each other and elastic fibres were found coursing between these cells. No external elastic membrane was identified and the adventitia consisted of loose collagen fibres and scattered fibroblasts. Pinocytotic vesicles were numerous in the endothelium and smooth muscle. These vesicles seemed, in some instances, to be most numerous in the endothelial and smooth muscle membranes bordering the internal elastic lamina. Cytoplasmic filaments and glycogen-like granules were present in endothelial cells as well as in smooth muscle. Coarser osmophilic granules were rarely present in the endothelium and smooth muscle close to the nucleus, mitochondria, endoplasmic reticulum or the Golgi apparatus.

ATPase activity was demonstrated in the major arterial circuit of the iris. Reaction product (lead phosphate) was distributed in the internal elastic lamina and lined endothelium and smooth muscle (Figs. 1 and 1*a*). High magnification studies showed the accumulation of reaction product beneath desmosomes between endothelial cells (Figs. 2 and 3). At times, minute particles of reaction product were found deep within pinocytotic vesicles of abutting endothelium and smooth muscle; in other instances, the amount of reaction product was greater and partly extruded from these vesicles into the adjacent interfibrillar spaces of the internal elastic lamina. Many sections showed that there was a greater accumulation of granules of reaction product on either side of the internal elastic lamina immediately adjacent to the plasma membranes of the endothelial and smooth muscle cells than in the centre of the internal elastic lamina. No significant amount of reaction product was found in (*a*) luminal pinocytotic vesicles of the endothelial cells, or in (*b*) pinocytotic vesicles of the smooth muscle that were not in close proximity to the internal elastic membrane.

These findings suggest that both the endothelial and smooth muscle cells play a significant part in the maintenance of ATPase activity in the space subjacent to endothelial desomosomes and in the interfibrillary spaces of the internal elastic lamina of the major arterial circuit of the iris. ATPase activity seems to be highly selective in its localization in this arterial circuit. Activity of this enzyme appears to be greater just beneath desmosomes of the endothelium and in cytoplasmic pinocytotic vesicles of endothelial and smooth muscle cells abutting the internal elastic lamina. These observations suggest that ATPase is extruded into these extracellular spaces by way of selective pinocytotic activity of the endothelium and first layer of smooth muscle that border the internal elastic lamina. It is possible that a degree of commensality exists between these two different cellular elements with higher requirements for the release of high-energy phosphate bonds for transport of nutrients or other substances across the interface of the internal elastic lamina. In this respect, it is noteworthy that no ATPase activity was demonstrated in the luminal pinocytotic vesicles of the lining endothelium nor in the pinocytotic vesicles of smooth muscle which were not in close proximity to the internal elastic lamina.

I thank J. R. Guzmán-Rivero, C. Calloway and B. O. Spurlock for technical assistance in this work, which was supported by U.S. Public Health Service grants.

A METHOD FOR ESTIMATING FREE ASPARAGINE AND GLUTAMINE IN BIOLOGICAL FLUIDS AS TRINITROPHENYL DERIVATIVES

By DR. J. D. BROOME
Cancer Research Unit, University of Alberta, Edmonton, Canada, and
Department of Pathology, New York University Medical Center, New York*

THIS article describes a method for the separate measurement of free asparagine and glutamine in small quantities of biological fluids containing 0·5–100 μg of each. It has proved equally suitable for extracts of animal tissues and for 0·5–1·0 ml. samples of blood or plasma. In simplicity and sensitivity the method has considerable advantages over others that are available at present[1–4].

* Present address.

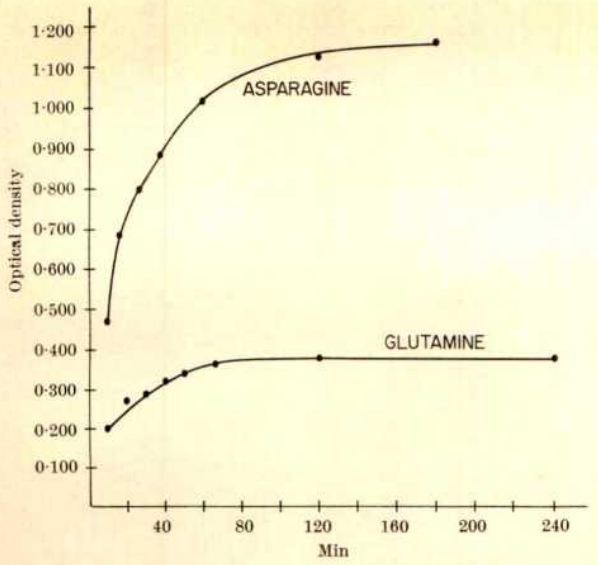

Fig. 1. Rates of trinitrophenylation of L-asparagine and L-glutamine. Incubation mixtures (39° C) consisted of chromatographically homogeneous L-asparagine 0·4 μmoles in 5 ml., 1·5 M phosphate buffer (*p*H 7·6) 0·2 ml., picrylsulphonic acid (Nutritional Biochemicals Corporation, Cleveland) 0·4 mg in 1 ml.; 0·5 ml. aliquots added at intervals shown to 0·5 ml. N hydrochloric acid to terminate the reaction (ref. 5). Water (5 ml.) added before making *O.D.* readings at 340 mμ. With L-glutamine (chromatographically homogeneous) a similar procedure was followed, but 0·2 ml. portions of the reaction mixture were used

In initial experiments, dinitrophenyl derivatives of asparagine and glutamine were prepared, but under conditions necessary for full derivatization large amounts of dinitrophenol accumulated which proved tedious to remove. To avoid this difficulty an alternative method was found in the preparation of 2,4,6-trinitrophenyl derivatives (TNP) using picryl sulphonic acid, according to a reaction recently described by Okuyama and Satake[5].

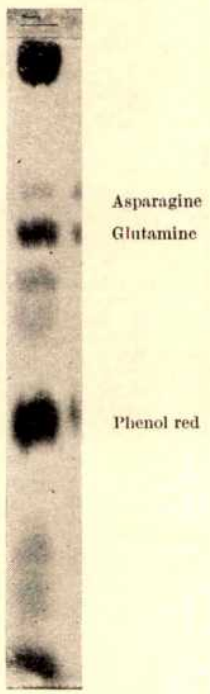

Fig. 2. Chromatography of amino-acid derivatives from tissue extract. Thymuses of 6 *C57/BL* mice (total weight 245 mg) homogenized in 13 ml. picric acid. A 5 ml. portion treated as described in text. Known samples of TNP derivatives of L-asparagine and L-glutamine run in parallel. (Whatman No. 4)

It is possible to separate out TNP derivatives of asparagine and glutamine by one-dimensional chromatography using tert-amyl alcohol saturated with phthalate buffer at *p*H 7·5, modifying the system of Blackburn and Lowther[6].

The stages of the procedure were as follows:

(1) *Protein precipitation with picric acid.* 0·5–1·0 ml. blood, plasma or serum was mixed with a 1 per cent solution of picric acid to a final volume of 6 ml., and the protein precipitate removed by centrifugation. Tissue samples weighing 50–800 mg were homogenized with 13 ml. picric acid solution in a Lourdes 'Omnimix' at 16,000 r.p.m. for 2 min. Filtration of the homogenate was preferable to centrifugation, owing to the tendency of fat-containing material to form a surface scum.

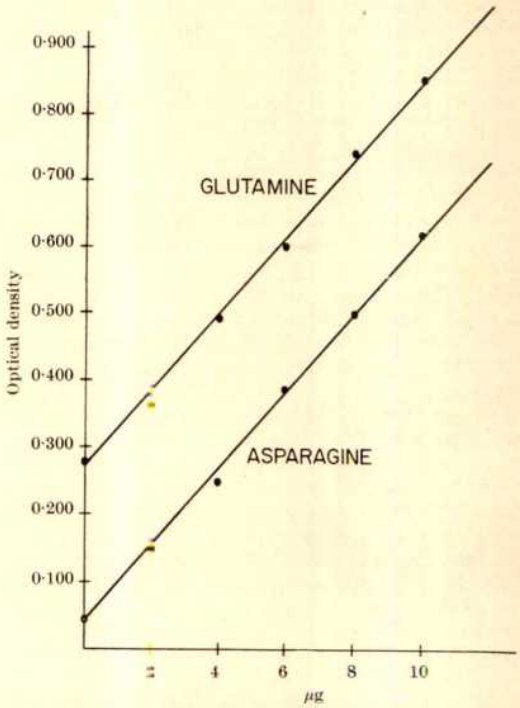

Fig. 3. Quantitation of TNP derivative formation from known amounts of L-asparagine monohydrate and L-glutamine added to samples of horse serum (1 ml.) and treated as described in the text. Eluates from chromatograms in 1 ml. water

(2) *Removal of excess picric acid.* 5 ml. quantities of protein-free supernatant were placed in stoppered test-tubes and acidified with one drop of 10 N hydrochloric acid. 5 ml. of ethyl acetate was then added and the layers gently mixed, avoiding the formation of an emulsion. After 2 washes picric acid was almost completely extracted from the aqueous layer. The remaining picric acid and dissolved ethyl acetate were removed by two extractions with 5–10 ml. ether, the residues of which were then removed at 37° C under reduced pressure.

(3) *Trinitrophenylation.* One drop of 0·17 per cent phenol red was added to the sample, followed by 0·2 ml. 1·0 M phosphate buffer and sufficient 1 N sodium hydroxide to make the colour of the indicator cherry-red, that is, *p*H 7·7. 1 ml. of 0·04 per cent picryl sulphonic acid was then added and the mixture incubated at 40° C for 3 h, which brought about complete trinitrophenylation (Fig. 1). As TNP derivatives of amino-acids are light-sensitive, this and further procedures were conducted as much as possible in the dark. It was found convenient to cover reaction tubes in aluminium foil.

(4) *Extraction of TNP derivatives of amino-acids.* After cooling the reaction mixture to room temperature

1 N hydrochloric acid was added until on testing with indicator paper the *p*H was reduced to 1·5–2·0. Amino-acid derivatives were then extracted in three thorough washes of 5 ml. ether, which were pooled in a 70 ml. centrifuge tube. The extract was dried at 35° C in a current of air.

(5) *Chromatography.* The dry extract of TNP amino-acids was dissolved in a few drops of moist peroxide-free ether. It was applied in a strip 0·5–1·5 in. long to chromatography paper (Whatman, Nos. 1, 4, or 3*MM*), thoroughly dried after saturation in 0·05 M phthalate buffer at *p*H 7·5. The chromatogram was developed by the descending technique using tert-amyl alcohol saturated with phthalate buffer; an over-night run was usually found adequate for the thinner papers. To obtain optimal results the quality of the tert-amyl alcohol was particularly important. Practical grades (boiling point 100°–103° C) provided better results than more highly purified preparations with which there was a tendency for streaking to occur. With such materials, however, the addition of 0·5 per cent pyridine greatly improved the resolution. The *p*H of the phthalate buffer was also critical. At normally used *p*H values (6·0–6·5)[6], asparagine and glutamine derivatives did not separate, but at *p*H 7·5, when phthalate had very little buffering activity for alkali, excellent separation was obtained.

(6) *Elution from chromatograms.* When the chromatograms had been dried, asparagine and glutamine spots were rapidly located and marked under long-wave ultraviolet light. They were eluted in 0·5–2·0 ml. distilled water. Corresponding areas behind the amino-acid spots were removed for blanks. Optical density measurements were made at 340 mμ in the Zeiss *PMQ* II spectrophotometer.

Fig. 2 shows the separation that can be obtained between glutamine and asparagine in an extract from mouse thymic tissue. R_F values of TNP derivatives are as follows: asparagine, 0·16; glutamine, 0·23; glutamic acid, 0·02; aspartic acid, 0·01; cystine, 0·20 and 0·56; glutathione (GSH), 0·12.

TNP-asparagine appears in a perfectly distinct spot and no other substance has been found to occupy its place. A cystine derivative, however, does not always clearly separate from glutamine. As it is formed in small amounts in the systems now used (giving about 5 per cent of glutamine values) it does not seriously interfere with results. However, to obtain most accurate values for both asparagine and glutamine concentrations, a blank should be prepared by incubating an aliquot of protein-free and picric acid-free filtrate (stage 2) with 0·2 ml. dialysed guinea-pig serum (L-asparaginase) and 0·1 ml. of glutaminase preparation[3] at *p*H 7·5 and 38° C for 1 h. The enzymes are then precipitated with an excess (100 mg) of picric acid, and the remaining procedures followed.

Fig. 3 shows the relationship between known amounts of glutamine and asparagine added to horse serum and the optical densities of eluates from the chromatograms. Recoveries are 101 ± 3 per cent of those that can be obtained from simple aqueous solutions of the amino-acids. The asparagine derivative prepared as now described gives an apparent molar extinction coefficient of $1{\cdot}173 \times 10^4$, the glutamine derivative $1{\cdot}018 \times 10^4$. Such values are similar to those obtained by Okuyama and Satake for other amino-acids[5].

The method described has proved valuable in investigating changes in amino-acid levels of animals treated with L-asparaginase—an enzyme causing powerful and apparently specific inhibition of a number of transplanted tumours[7–9].

I thank Mrs. E. Ramsamooj and Mr. H. Baez for their technical assistance in this work, which was supported by grants from the National Cancer Institute of Canada and the National Cancer Institute, U.S. Public Health Service.

A FURTHER STUDY OF CATECHOLAMINE *O*-METHYLATION IN SCHIZOPHRENIA

By ARTHUR F. WAGNER, VINCENT J. CIRILLO, DR. M. A. P. MEISINGER, ROBERT E. ORMOND, DR. FREDERICK A. KUEHL, jun., and DR. NORMAN G. BRINK

Merck Sharp and Dohme Research Laboratories, Rahway, New Jersey

THE possibility that aberrant *O*-methylation in catecholamine metabolism is significant in the aetiology of schizophrenia was suggested by the pharmacological effects of a number of *para*-*O*-methylated catecholamines[1–3], and by the detection of an abnormal-*O*-methylated catecholamine metabolite in the urine of schizophrenics. Friedhoff and Van Winkle[4,5] were the first to report that 3,4-dimethoxyphenethylamine was excreted in the urine of a majority of schizophrenics but not in normal individuals. Later, they presented data derived from *in vivo* and *in vitro* studies to show that the di-*O*-methylated analogue is of endogenous origin[6]. Several investigators[7–9] confirmed the original observation of Friedhoff and Van Winkle on the unique occurrence of 3,4-dimethoxyphenethylamine in the urine of schizophrenics, but they reported significantly lower percentages of positive detections in the schizophrenic group. This discrepancy might arise from the varying percentages of acute and chronic schizophrenics in the several test groups. Others have reported contradictory data which suggest that the di-*O*-methylated derivative is not unique to schizophrenics and is probably of dietary origin[10–13]. That such derivatives are not unique to schizophrenia may also be inferred from a recent publication[14] describing the induction of akinesia in animals by di-*O*-methylated catecholamines, and associating these derivatives with the akinesia of Parkinson's disease. In this article and the succeeding one, data are also presented to suggest that abnormal *O*-methylation of catecholamines may not be a significant biochemical lesion in schizophrenia.

For the following *in vitro* investigations of catecholamine metabolism, autopsy specimens of liver and brain from normal and schizophrenic subjects were promptly frozen and stored in dry ice. Enzyme preparations were routinely made from a 10-g portion of liver or a 20-g portion of brain by homogenization at 4° C in 40 ml. of isotonic potassium chloride. After centrifugation for

10 min at 8,000*g*, the supernatant phase was decanted through coarse cheesecloth to remove the lipid layer.

For these metabolism investigations, a standard incubation procedure[15,16] was modified to the extent that each vessel contained 1·0 ml. of 0·5 M sodium phosphate buffer (*p*H 7·9), 0·5 ml. of 'Catron' (α-methylphenethylhydrazine, 5·6 mg/0·5 ml.), 0·2 ml. of *S*-adenosyl-L-methionine-methyl-^{14}C (10 μmoles, 10 μc./ml.), 0·2 ml. of dopamine (10 μmoles/ml.), 2·0 ml. of the filtrate, and 0·1 ml. of 0·5 M magnesium chloride. The *p*H of the incubation mixture was 7·6. Controls lacking dopamine were included in each series of determinations. The reaction vessels were flushed with nitrogen, stoppered, and incubated for 1·5 h at 37° C. The *p*H remained constant throughout the incubation.

At the end of incubation, 2 ml. of 0·5 M sodium borate buffer (*p*H 10) was added to the reaction mixture which was then adjusted to *p*H 10 with one drop of 10 N sodium hydroxide. The mixture was extracted[8] with three 4-ml. volumes of isoamyl alcohol–toluene (3 : 2). The organic phase was extracted with three 3-ml. volumes of 0·1 N sodium hydroxide to remove mono-*O*-methyl derivatives of dopamine, and then with three 1-ml. volumes of 0·05 N hydrochloric acid to remove di-*O*-methyl derivatives of dopamine. The acidic aqueous extract was reduced to dryness under a stream of nitrogen. The residue was dissolved in one drop of methanol and applied to a 20 cm × 20 cm thin layer of silica gel ('Silica gel *G*', E. Merck). The sample was flanked by 10 μg markers of the mono- and dimethoxy-phenethylamine analogues, and developed in butanol–ethyl acetate–15 N aqueous ammonia (3 : 1 : 1). The markers were sprayed with 0·2 per cent ninhydrin in pyridine–acetic acid–acetone (1 : 4 : 95), and the plate was heated at 100° C until the marker colours developed. The sample area was not sprayed because of the quenching effect of ninhydrin.

Fifteen consecutive 1 cm × 2·5 cm sections were marked in the sample area between the origin and the solvent front. The adsorbent in each section was scraped into a glass counting vial containing 20 ml. of a 4 per cent (w/v) 'Cab-O-Sil'—toluene scintillation solution consisting of 3·0 g of 2,5,diphenyloxazole and 100 mg of 1,4-*bis*(4-methyl-5-phenyloxazol-2-yl)-benzene per litre of toluene[17,18].

Radioactive counting of the contents of these vials for 10 min in a Packard model 3002 'Tri-Carb' liquid scintillation spectrometer gave a measure of enzymatic di-*O*-methylation. For a measure of catechol-*O*-methyltransferase (COMT) activity, a portion of the 0·1 N sodium hydroxide extract of the incubation mixture was counted in a toluene scintillation solution containing 30 per cent absolute ethanol.

Specimen	Diagnosis	Age (yr)	Sex	Post-mortem autop
3	Schizo	34		

For the complete procedure, the efficiency of recovery of 2-(3,4-dimethoxyphenyl)ethylamine-1-^{14}C hydrochloride was established as 40 per cent and the limit of its detection as 50 ng by standard techniques.

The results of the *in vitro* investigations are summarized in Tables 1 and 2. Although only one set of data is reported for each specimen, most were tested on at least three occasions and gave similar data within experimental error. On the basis of these data, liver tissue preparations from six schizophrenic and three normal individuals and brain tissue preparations from four schizophrenic and one normal individual failed to convert dopamine to 3,4-dimethoxyphenethylamine. That such inactivity might be attributed to a loss of enzyme activity in necrotic tissue is readily conceded, but it is suggested that the relatively high COMT activity exhibited by these specimens is a valid indication of normal enzyme integrity.

At the conclusion of our *in vitro* investigations, we were informed of an independent investigation at Rockland State Hospital, Orangeburg, N.Y., in which 100 μc. of 3,4-dihydroxyphenylalanine-2-^{14}C was administered to two chronic schizophrenic patients. Though the courtesy of Dr. W. Sacks of that institution we were given a 24 h urine collection from each of these patients; equal portions of these specimens were subjected to extraction and two-dimensional thin-layer chromatography[8] to determine the levels of 3,4-dimethoxyphenethylamine and were examined for 3,4-dimethoxyphenylacetic acid[19]. Appropriate sections of adsorbents were scraped from the plates, eluted and counted as already described.

The *in vivo* data summarized in Table 3 suggest that 3,4-dimethoxyphenethylamine and 3,4-dimethoxyphenylacetic acid are not metabolites of 3,4-dihydroxyphenylalanine in the chronic schizophrenic.

OCCURRENCE OF 3,4-DIMETHOXYPHENYLACETIC ACID IN URINES OF NORMAL AND SCHIZOPHRENIC INDIVIDUALS

By DR. FREDERICK A. KUEHL, jun., ROBERT E. ORMOND and W. J. A. VANDENHEUVEL

Merck Sharp and Dohme Research Laboratories, Rahway, New Jersey

DERANGEMENTS of amino-acid metabolism have been implicated in a variety of mental disorders[1]. In particular, recent investigations have directed our attention to a possible aberrant para-*O*-methylation of 3,4-dihydroxyphenethylamine (dopamine) in schizophrenia. Friedhoff and Van Winkle[2] reported that 3,4-dimethoxyphenethylamine was present in the urine of a majority of the schizophrenic patients studied, but was not excreted by normal subjects. Sen and McGeer[3], using a combined paper strip–gas chromatographic method, were able to detect the amine in urines of eleven of twenty-two schizophrenics, but no normal subjects were examined. In an extensive clinical study, Bourdillon *et al.*[4], using a slight modification of the Friedhoff technique, were able to detect a 3,4-dimethoxyphenethylamine-like component in the urine of many schizophrenics. On the other hand, some recent publications[5] record the failure to detect this amine in urines of schizophrenic patients. Friedhoff and Van Winkle[6] have reported that di-*O*-methylation of dopamine occurs *in vitro* when the substrate is incubated with a liver biopsy homogenate obtained from a schizophrenic patient known to excrete 3,4-dimethoxyphenethylamine, and that di-*O*-methylation of administered labelled dopamine can be demonstrated *in vivo*; however, others have been unable to confirm this observation[7]. Indeed, the identity of the urinary amine (the "pink spot", as it has been called[4]) has not been determined unequivocally, and the relationship of 3,4-dimethoxyphenethylamine to schizophrenia remains controversial.

We were unable satisfactorily to measure 3,4-dimethoxyphenethylamine in urines of schizophrenics by the Friedhoff paper strip technique, but using an ion exchange resin two-dimensional thin-layer chromatographic method[8] were able to demonstrate the presence of a compound indistinguishable from it in seven of twelve urine specimens from schizophrenic patients, whereas none was found in urines of ten normal subjects examined. The amounts measured, however, were low—3–10 μg/day, compared with the 20–50-μg value reported by Friedhoff.

The major metabolic end-products of the catecholamines are the corresponding acids resulting from deamination and oxidation—the vanilmandelic acid content of urine is normally considered to represent a major portion of metabolized epinephrine and norepinephrine. Evidence has been presented that administered 3,4-dimethoxyphenethylamine[6] follows the same metabolic pathway when administered to humans. This was also shown to be true with rats; animals treated with this ^{14}C-labelled amine excreted 3,4-dimethoxyphenylacetic acid[9] almost exclusively, but with a small portion of the parent amine unless a monoamine oxidase inhibitor was administered. Thus it is apparent that a met[illegible] to determine 3,4-dimethoxyphenylacetic [illegible] would permit an indirect estimation of [illegible] article describes such a method and [illegible] from investigations of urine speci[illegible] of schizophrenic and normal [illegible]

amount of 3,4-dimethoxyphenylacetic acid isolated.) When the chloroform layer had been washed with a small volume of water it was made alkaline by the addition of 2·5 ml. of 0·04 N sodium hydroxide and concentrated *in vacuo* to 5–10 ml. The aqueous layer was removed and combined with two additional aqueous extracts of the chloroform layer. The acids were separated from the aqueous solution by re-extraction into chloroform at *p*H 1·5–2·0. The residue obtained by evaporation of the chloroform extract under a nitrogen stream was redissolved in a small volume of that solvent and applied to a 20 × 20-cm silica gel *G* thin-layer plate. After development with the upper phase of a solvent mixture consisting of glacial acetic acid, benzene and water (3 : 2 : 1) in an atmosphere saturated with the lower phase, the 3,4-dimethoxyphenylacetic acid zone was located by visualization of guide spots of the acid (introduced initially adjacent to the urinary extract zones) with ultra-violet light, or by spraying with alkaline permanganate. The appropriate area was scraped into a small column containing a plug of glass wool and the 3,4-dimethoxyphenylacetic acid zone eluted with 6 ml. of chloroform containing acetic acid (5 per cent); the solvent was removed under a nitrogen stream.

The analysis of urinary aromatic acids (as their methyl esters) by gas chromatography is well established[10]. In order to increase confidence in the identification of methyl 3,4-dimethoxyphenylacetate two stationary phases of different chemical nature were used routinely—the polar polyester neopentylglycol adipate (NGA)[11] and the relatively non-polar two-component phase *F*-60-*Z* (ref. 12). (In the early stages of this investigation, when only one gas chromatography column was used and before the thin-layer chromatography conditions had been optimized, it was observed with several samples that, following acetylation, a major decrease in peak size (gas chromatogram) occurred, indicating that before acetylation an acylable compound was eluted at the same rate as methyl 3,4-dimethoxyphenylacetate. Under the final established set of experimental conditions this phenomenon was not encountered.) A second more polar polyester, ethyleneglycol succinate (EGS)[11], was used in selected instances. (Gas chromatographic conditions, NGA: 8 per cent NGA on 80–100-mesh 'Gas Chrom *P*' prepared according to the method of Horning *et al.*[13]; 6 ft. × 4 mm glass U-tube; 170° C; 13 lb./in.^{2}. Gas chromatographic conditions, *F*-60-*Z*: a mixture of 4·9 per cent *F*-60 (a methylpolysiloxane polymer containing a low percentage of *p*-chlorophenyl groups; Dow Corning Corp.) and 0·9 per cent EGSS-Z (a copolymer from ethylene glycol, succinic acid and a methylphenyl-siloxane monomer; Applied Science Labs., Inc.) on 80–100-mesh 'Gas Chrom *P*' prepared [illegible] × 4 mm glass U-tube; 150° C; 9 lb./in.^{2}. [illegible]ic conditions, EGS: 8 per cent ethyl[illegible]60–100-mesh 'Gas Chrom *P*' pre[illegible]m glass U-tube; 185° C; [illegible]ethyl 3,4-dimethoxy[illegible] min. *F*-60-*Z*:

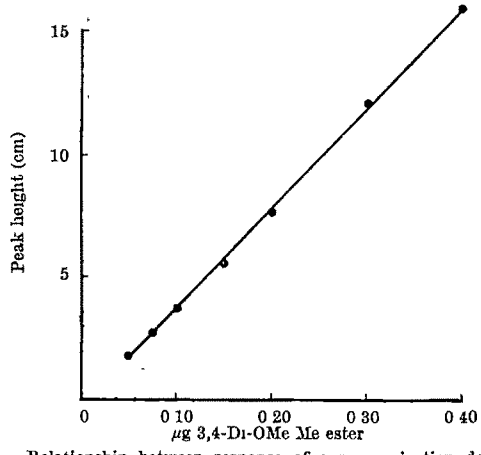

Fig. 1. Relationship between response of argon ionization detector (peak height in cm) and sample size (μg methyl 3,4-dimethoxyphenylacetate) with an *F*-60-*Z* column

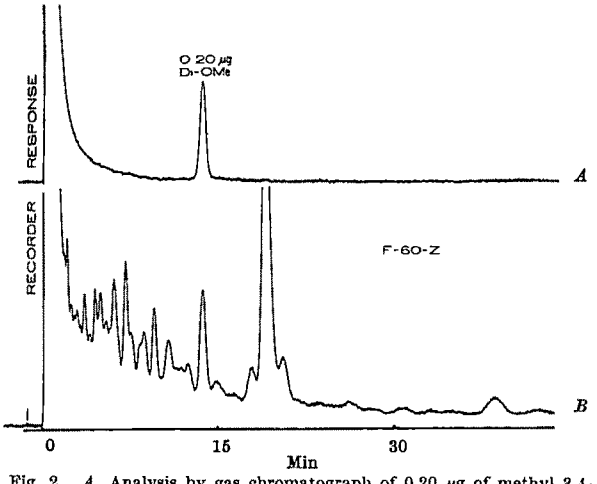

Fig. 2. *A*, Analysis by gas chromatograph of 0 20 μg of methyl 3,4-dimethoxyphenylacetate. *B*, Analysis by gas chromatograph (following esterification with diazomethane) of the 3,4-dimethoxyphenylacetic acid zone from the thin-layer chromatography of the urine of an acute schizophrenic individual This sample is equivalent to 5 ml. of urine, one two-hundred and fiftieth of a 24 h urinary output See text for column conditions

stream of nitrogen) some homovanillic acid, a normal constituent of urine, might be converted to methyl 3,4-dimethoxyphenylacetate was ruled out on the following grounds. Homovanillic acid was well separated from 3,4-dimethoxyphenylacetic acid by thin-layer chromatography, and in the few instances when methyl homovanillate was observed on the gas chromatograms (retention time relative to methyl 3,4-dimethoxyphenylacetate: *F*-60-*Z*, 0·92; NGA, 1·32) the quantities were too small to account for more than a minor fraction of the methyl 3,4-dimethoxyphenylacetate peak, since under the conditions of methylation less than 1 per cent of homovanillic acid could be converted to methyl 3,4-dimethoxyphenylacetate.

The linearity of response of the argon ionization detection system (800 V) to methyl 3,4-dimethoxyphenylacetate was determined by a dilution procedure. Fig. 1 shows a plot of peak height (cm) versus sample size (μg), and the relationship found for the system indicates that mass linearity existed at the level of sample size of interest for our work. In order to allow for slight day-to-day changes in the sensitivity of the detector and the operating conditions of the gas chromatograph, the detector response for known amounts of methyl 3,4-dimethoxyphenylacetate was determined during each series of sample analyses; the amount of the ester present in the urinary sample was then read from the plot. The reproducibility of detector response was excellent; for example, three consecutive injections of 0·15 μg of methyl 3,4-dimethoxyphenylacetate

Table 1. 3,4-DIMETHOXYPHENYLACETIC ACID CONTENT OF URINES FROM NORMAL AND THREE TYPES OF SCHIZOPHRENIC INDIVIDUALS (μg/g creatinine)

Normal	Acute	Sub-acute	Chronic
26	32	20	27

* μg/l

gave an average peak height of 6·78 ± 0·05 cm. Reproducibility of data concerning the 3,4-dimethoxyphenylacetic acid content of urinary fractions was also satisfactory. After an interval of several days a sample which had exhibited a 3,4-dimethoxyphenylacetic acid level of 22 μg/g creatinine on EGS (19 on *F*-60-*Z*) was re-submitted for analysis on EGS on a double blind basis; the second value was 23 μg/g creatinine. (In general, values found with the different columns agreed to a satisfactory extent. One urinary sample, analysed on each of the three columns, gave values of 31 μg/g creatinine (*F*-60-*Z*), 31 μg/g creatinine (NGA) and 29 μg/g creatinine (EGS). The necessity for the use of multiple columns is well illustrated by the case of one urine which exhibited a high value (greater than 100 μg/g creatinine) on *F*-60-*Z*, but proved to be negative on NGA.)

The specificity and accuracy of the procedure were established by adding known quantities of 3,4-dimethoxyphenylacetic acid to distilled water or urine. Thus the addition of 3·0 μg of acid to 100 ml. of water gave a recovery of greater than 90 per cent, and the addition of 3 μg of acid to 100 ml. of a urine, previously shown to contain 3 μg acid/100 ml., led to a new value of 5·8 μg/100 ml.

Additional evidence for the identification of 3,4-dimethoxyphenylacetic acid was obtained by examining samples from the urine of a sub-acute schizophrenic and a normal individual on an *LKB* model 9000 gas chromatograph mass spectrometer using the molecular separator of Ryhage[14] developed at the Mass Spectrometry Laboratory of the Karolinska Institute, Stockholm. In both cases the peak in the gas chromatogram corresponding to methyl 3,4-dimethoxyphenylacetate was found to possess *m/e* values for the molecular ion (210) and for fragmentation products (for example, 151 and 121) in agreement with those of an authentic specimen of the compound.

As can be seen in Table 1, 3,4-dimethoxyphenylacetic acid was found to be present at levels of 10–30 μg/g creatinine equivalent in a large number of the urines examined. (It has been reported[10] that, under conditions allowing the detection of 300 μg/g creatinine, no 3,4-dimethoxyphenylacetic acid was found in normal urine.) No truly significant difference could be detected between the schizophrenic and normal urines investigated. In addition to the subjects detailed in Table 1, an additional fifty-six individuals were examined on a qualitative or semi-quantitative basis for their urinary excretion of 3,4-dimethoxyphenylacetic acid—here also no significant difference could be detected between the schizophrenic and normal group.

The identity of the urinary excretion product described in this article as 3,4-dimethoxyphenylacetic acid is suggested by chemical properties and thin-layer chromatography, strengthened by gas chromatography on a variety of columns and confirmed by mass spectrometry. In addition, the quantitative nature of the method is well established by accepted methods. (For a brief discussion of the need for reliable methodology in this field see ref. 15.) Therefore, consideration of these data requires some qualifications concerning the suggestion that 3,4-dimethoxyphenethylamine is a compound unique to the urines of schizophrenics. Although the presence of this amine in urine of schizophrenic patients has been indicated

by some investigations[2-4,6,8], including our own, the identity of the compound is based mainly on migration rates on paper or thin-layer plates, and thus cannot be considered to be rigorously established. It may well be noted here that a number of urine specimens examined in our present investigations for the acid metabolite were also studied for the presence of 3,4-dimethoxyphenethylamine by the method previously described[8], all with negative results. Thus our initial interpretation of the observation that the amine is present in urines of five of twelve acute and two of ten chronic schizophrenic patients must be altered in the direction of non-correlation of the occurrence of the amine with schizophrenia. It should be noted, however, that in the present investigations less excessively acute patients were available for study. The possibility that, under conditions of hyperexcitability, not necessarily related to schizophrenia, the di-*O*-methylated amine could be produced by normal COMT occurred to us as an explanation of the occurrence of the amine. Accordingly, we studied the soluble catechol-*O*-methyl transferase[16] of rat liver for the ability to di-*O*-methylate dopamine under a variety of conditions including large excesses of enzyme and *S*-adenosyl-methionine as well as varied amounts of the dopamine substrate. In no case was 3,4-dimethoxyphenethylamine detected although the normal mono-*O*-methyl derivatives of dopamine were formed in abundance based on the incorporation of label from *S*-adenosyl-methionine-methyl-^{14}C. The possibility that the recently described[17] microsomal catechol-*O*-methyl-transferase could account for the formation of 3,4-dimethoxyphenethylamine was similarly investigated, but again with negative results. The observation by Barbeau *et al.*[18] that urine of individuals suffering from Parkinson's disease contains large quantities of 3,4-dimethoxyphenethylamine is of interest and further questions the validity of the concept that the occurrence of 3,4-dimethoxyphenethylamine as a urinary metabolite is unique to schizophrenia. From this observation it can be speculated that the abnormal methylation in Parkinsonians causes a diminution of basic dopamine-levels and could explain the favourable response of such individuals to administration of dihydroxyphenylalanine. We are at present examining the urines of patients with Parkinson's disease for the presence of 3,4-dimethoxyphenylacetic acid.

The possibility that urine levels of 3,4-dimethoxyphenylacetic acid bear no relationship to amine-levels is remote, assuming no fault in monoamine oxidase activity in schizophrenics, as it has been established that in both human subjects and rats[9] administered 3,4-dimethoxyphenethylamine is largely excreted as the acid. Indeed, the endogenous nature of the amine has been questioned; some suggest it to be of exogenous origin[5]. We also feel that the endogenous nature of the metabolite is open to question, because our studies with urine samples from a chronic schizophrenia patient who had received labelled dihydroxyphenylalanine failed to indicate the presence of either ^{14}C-labelled 3,4-dimethoxyphenethylamine or the corresponding 3,4-dimethoxyphenylacetic acid, although gas chromatography of the eluted area on the thin-layer plate revealed the presence of 'normal' amounts of the unlabelled acid.

In summary, we have developed a sensitive method for determining 3,4-dimethoxyphenylacetic acid in urine. Because no significant differences could be detected in the amount of acid present in urines of schizophrenic or normal individuals, we must conclude either that the excretion of 3,4-dimethoxyphenethylamine is not characteristic of schizophrenia or that the amount of 3,4-dimethoxyphenylacetic acid present in urine is not a true reflexion of the amount of 3,4-dimethoxyphenethylamine present. On the basis of evidence at present available we prefer the former interpretation.

We thank Dr. S. Arthur Sugarman of New Jersey Neuropsychiatric Center; Dr. Hans Freymuth, Dr. Shaw Perry and Dr. Walter Hill of Trenton State Hospital; Dr. W. Sacks, Dr. Nathan Kline and Dr. A. Esser of Rockland State Hospital; and Dr. Arnold Friedhoff of New York University School of Medicine for urine specimens used in these studies. We also thank Prof. R. Paoletti and Mr. O. Holmström for making the *LKB* model 9000 gas chromatograph mass spectrometer available to us for the analysis of samples during the Second International Course on Methods for Lipid Research, Milan, Italy, in September 1965; Mr. S. Wikström for carrying out the analyses; and Drs. P. Capella, J. McCloskey and J. Sjövall for their help in interpreting the spectra.

DIFFUSION-EXCHANGE RESPIROMETER USING THE CARBON DIOXIDE ELECTRODE

By DR. CREIGHTON R. JENSEN and DR. S. D. VAN GUNDY
Department of Nematology
AND
DR. L. H. STOLZY
Department of Soils and Plant Nutrition, University of California, Riverside

TYPES of respirometers may be classed as either open or closed systems. The latter, such as the Warburg respirometer, generally measure the change with time of pressure, volume, or some other variable from which the rate of oxygen uptake (or carbon dioxide output) is deduced. The open-system respirometer, however, can be designed to indicate uptake or output rates directly by measuring the change in concentration of oxygen or carbon dioxide in air flowing through the respirometer at a known, constant rate. Nevertheless, the more extensive apparatus

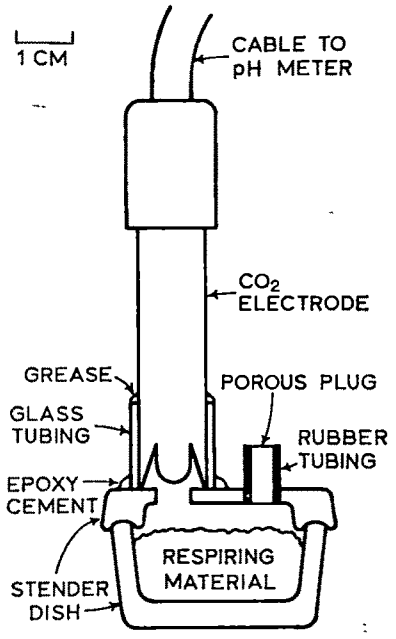

Fig. 1. A diffusion-exchange microrespirometer

required to produce, regulate and monitor the air stream has placed the open-system respirometer at a disadvantage compared with the simpler closed-system types.

The possibility of exchanging air in an open-system respirometer by the process of diffusion rather than mass flow has not apparently been considered previously, although Connelly *et al.*[1] measured the respiration of peripheral nerve with an oxygen cathode by a method based on the relationship of oxygen concentration, uptake and diffusion in the nerve trunk. Using a Severinghaus type of potentiometric carbon dioxide electrode[2] and diffusion exchange, we have devised a new type of open-system respirometer that measures carbon dioxide evolution and has the simplicity of closed-system types.

Essentially, the respirometer (Fig. 1) consists of a chamber containing the respiring material, an electrode to monitor the partial pressure of carbon dioxide within the chamber, and a porous plug in the chamber wall. Gas exchange with the external atmosphere occurs by diffusion through the porous plug in response to concentration differences. Additionally, the total pressure is kept atmospheric by equilibration through the porous plug. As will be shown, the partial pressure of carbon dioxide in the chamber under steady-state conditions is proportional to the rate of carbon dioxide evolution (respiration rate).

The rate of change of the quantity of gaseous carbon dioxide within the chamber at any instant is equal to the rate of carbon dioxide evolution by the respiring material minus the rate of loss by diffusion out through the porous plug, that is:

$$d\rho/dt = (rM/V - J)/v \quad (1)$$

where ρ is the density of carbon dioxide in the chamber in g/μl. of gas volume, t is time in min, r is the rate of carbon dioxide evolution in N.T.P. μl./min, M is the molar weight of carbon dioxide, V is the molar volume (22·41 l./mole), v is the gas volume of the chamber in μl. and J is the rate of diffusion of carbon dioxide out of the chamber in g/min.

If ρ does not change too rapidly:

$$J = h(\rho - \rho_0) \quad (2)$$

where ρ_0 is the density of carbon dioxide in the external atmosphere and h is the permeability coefficient in μl./min of the porous plug for carbon dioxide. Equations (1) and (2) combined are:

$$d\rho/dt = \frac{rM/V - h(\rho - \rho_0)}{v} \quad (3)$$

Equation (3) can be written in terms of the partial pressure p (in mm of mercury) of carbon dioxide by utilizing the ideal gas law:

$$p = \rho RT/M$$

where R is the gas constant (62·36 l. mm deg^{-1} mole^{-1}) and T is the temperature (°K). Equation (3) then is:

$$dp/dt = \frac{rRT/V - h(p - p_0)}{v} \quad (4)$$

where p_0 is the partial pressure of carbon dioxide in the external atmosphere.

Integration of equation (4), assuming that r is constant, yields:

$$p = (p_c + rRT/hV)(1 - e^{-ht/v}) + p_1 e^{-ht/v} \quad (5)$$

where $p = p_1$ at $t = 0$. The exponential terms become zero as the steady-state is approached and equation (5), solved for r, then is:

$$r = hV(p - p_0)/RT = k(p - p_0) \quad (6)$$

where $k = hV/RT$. Thus $p - p_0$ is proportional to r in the steady-state and may be used as a measure of r if h can be evaluated.

Determination of h may be readily done by flushing the empty chamber with carbon dioxide, then closing it and recording p as the carbon dioxide diffuses out through the porous plug. Equation (5) with $r = 0$ applies to this case; in logarithmic form it is:

$$\ln(p - p_0) = \ln(p_1 - p_0) - ht/v \quad (7)$$

Solving for h,

$$h = 2{\cdot}303v(\log[p_1 - p_0] - \log[p - p_0])/t \quad (8)$$

For air, $p_0 \sim 0{\cdot}2$ mm and is negligible in equation (8) if p and p_1 are large. The carbon dioxide electrode potential varies linearly with log p (for $p > 15$ mm); and, since h is constant, the potential should, according to equation (8), decrease linearly with time as the carbon dioxide diffuses out of the chamber. We verified this linearity experimentally as shown in Fig. 2. The slope of the line B is $-(\log[p_1 - p_0] - \log[p - p_0])/t$. By weighing the chamber before and after filling with water, v may be determined, and h and k then calculated.

For $(p - p_0) < 15$ mm, the electrode potential (curve A) in Fig. 2 departs from the linear relationship (B) of equation (8). This departure results partly from p_0 being significant at low p, but it is largely a characteristic of the electrode observed previously[3]. After the porous plug has been calibrated, it is better to make respiration measurements in this lower range of p to avoid any effects of higher carbon dioxide evels on the respiring material. Consequently, the electrode reading must be corrected and the curves in Fig. 2 may be used as a convenient nomogram for this purpose. The steady-state electrode potential from a respiration measurement is first located on the curve A. The point on the line B at the same abscissa then is that for $\log(p - p_0)$, and $p - p_0$ thus determined may be used in equation (6) to calculate r. Or, for a particular porous plug and temperature (k value), Fig. 2 could be scaled to read r directly.

In using Fig. 2 to obtain $p - p_0$, p_0 is assumed to be the same as when the curve was determined. Fluctuations of p_0, if not extreme, will introduce very small errors because p_0 itself is small for air. A porous plug with h too large (or a chamber with v too small) should not be used to obtain calibration curves as in Fig. 2, because the slope

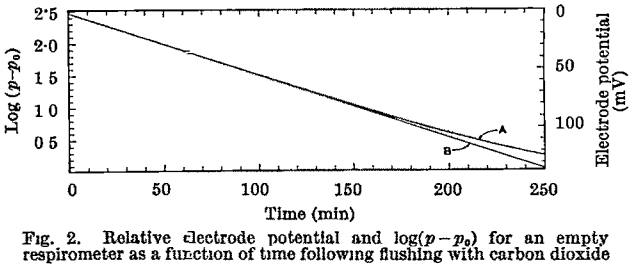

Fig. 2. Relative electrode potential and $\log(p - p_0)$ for an empty respirometer as a function of time following flushing with carbon dioxide

will then be great enough that a significant error from lag of the electrode response will be introduced.

A correction of the electrode potential for drift should be made occasionally by calibration with a gas of known carbon dioxide level (greater than or equal to 2 per cent to be in the region where A and B coincide in Fig. 2).

Fig. 1 shows a stender preparation dish converted to a respirometer which we have used for soil respiration measurements. Two holes were drilled in the lid, one for the porous plug and the other for the electrode. The rim of the dish was sealed with grease when a measurement was made. The soil was incubated in the same dish with an ordinary lid (ungreased) prior to measurement and was oven-dried and weighed in the same dish following measurement. The electrodes we used were temperature-compensated and kindly provided by Dr. G. Matsuyama, Beckman Instruments, Inc., Fullerton, California. Electrode potential was measured by a Beckman model 76 pH meter with an attached recorder. A special adaptor box between the electrode and pH meter contained temperature compensation circuitry.

Fig. 3 is a typical respiration measurement curve showing the approach to a steady-state carbon dioxide partial pressure in accordance with equation (5). The respiring material was Yolo silt loam with added sucrose. The time required to reach a steady state is 1–2 h. This long time is a disadvantage of the method. However, respiration rates that change slowly may be followed continuously with good accuracy once the steady state is approximated. Equation (5) indicates that the approach to a steady state may be hastened by increasing h and decreasing v. But increasing h reduces the steady-state value of p with a concomitant loss of sensitivity. Preferably, v should be reduced by filling the chamber as full as possible with the respiring material.

We made porous plugs as follows: 12 per cent by weight of solder glass (Code 7570, 325 mesh, from Corning Glass Works, Corning, New York) was mixed with 50μ-diameter glass beads ('Superbrite 660–5005', from Minnesota Mining and Manufacturing Co., Saint Paul, Minnesota) and poured into a length of 4-mm-inner-diameter glass tubing which served as a mould. On heating to ~600° C, the solder glass melted and formed capillary films at the contact points of the glass beads, thus cementing the beads into a porous solid when slowly cooled. The plugs were cut to length, removed from the glass tubing and inserted in tight rubber tubing so that only the ends were exposed. The dimensions of a plug for a given value of h could be approximately predetermined since h varies directly with the cross-sectional area and inversely with the length of the plug. The range of the respirometer can be prescribed by using a plug of appropriate h value (see equation (6)) and a chamber of such volume v as to give a suitable equilibration time according to equation (5).

The diffusion coefficient of carbon dioxide into air is nearly proportional to T^2 (ref. 4). Hence h should vary linearly with T^2 and k should vary linearly with T. For example, for a porous plug with $k = 0{\cdot}287$ μl./min/mm at 25° C we obtained a linear temperature coefficient from 14° to 33° C of 0·00228 μl./min/mm/°C. The departure of curve A from line B in Fig. 2 is also temperature dependent. For the electrodes we used, a single calibration curve could be used over a range of 5° without significant error.

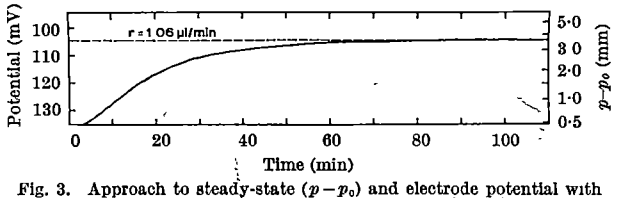

Fig. 3. Approach to steady-state ($p - p_0$) and electrode potential with time after closure of a respirometer containing respiring soil. $k = 0{\cdot}291$ μl./min/mm

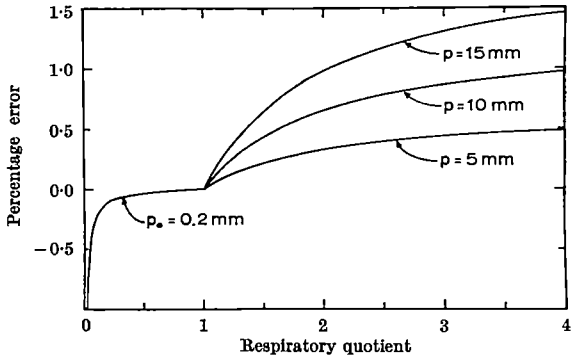

Fig. 4. Percentage error of r resulting from mass flow as a function of the respiratory quotient

Movement of the external air can also affect h by changing the thickness of the diffusive air layer at the outer end of the porous plug. For example, for a porous plug at 26·5° C, k was 4·5 per cent greater in a plant growth chamber with rapid air circulation than in a still room. Hence, average air movement during measurements should be similar to that during calibration of the plug.

If the respiratory quotient differs from unity, a total pressure change will develop within the chamber and produce a mass flow of air into or out of the chamber depending on whether the quotient is less than or greater than one. The mass flow of carbon dioxide may be approximately accounted for in the steady state ($dp/dt = 0$) by adding a term to equation (4):

$$0 = (rRT/V) - h(p - p_0) - \frac{760T(r-x)}{273P}p, \quad \mathrm{RQ} > 1 \qquad (9)$$

$$0 = (rRT/V) - h(p - p_0) - \frac{760T(r-x)}{273P}p_0, \quad \mathrm{RQ} < 1 \qquad (10)$$

where x is the rate of oxygen uptake in N.T.P. μl./min, P is the total (atmospheric) pressure in mm of mercury, and RQ ($= r/x$) is the respiratory quotient. If equations (9) and (10) are re-arranged and compared with equation (6), the error due to mass flow will be seen to be approximately:

$$760V(r-x)p/273RP \sim 0{\cdot}0013(r-x)p, \quad \mathrm{RQ} > 1$$
$$760V(r-x)p_0/273RP \sim 0{\cdot}0013(r-x)p_0, \quad \mathrm{RQ} < 1$$

The percentage error is obtained by multiplying by $100/r$.

$$\text{Percentage error} = 0{\cdot}13(1 - [x/r])p, \quad \mathrm{RQ} > 1 \qquad (11)$$
$$\text{Percentage error} = 0{\cdot}13(1 - [x/r])p_0, \quad \mathrm{RQ} < 1 \qquad (12)$$

Plots of equations (11) and (12) in Fig. 4 show that the mass flow error is less than 1 per cent for the usual range of RQ.

One advantage of the method is that v does not appear in equation (6). Therefore, once calibrated, using a chamber of known v, the porous plug may be used with other chambers of unknown volume. Also, no correction need be made for the volume of the respiring material; this is advantageous for material such as soil the volume of which cannot be measured directly. This fact, together with the fact that the interior of the chamber is at atmospheric pressure, makes convenient forms of the respirometer in which only an intact portion of an organism, for example, plant roots, can be sealed into the chamber and its carbon dioxide output measured.

Both h and $p - p_0$ can be determined to three significant figures with careful measurements, thus determinations of r to within 1 per cent should be possible for RQ values near unity.

LETTERS TO THE EDITOR

PLANETARY SCIENCE

Sediment Transport by the Antarctic Bottom Current on the Bermuda Rise

THE basic pattern of bottom water circulation in the Atlantic Ocean was well described in the reports of the *Meteor* Expedition[1]. On the basis of dynamic topography, Wüst[2] calculated average current velocities of 2–15 cm/sec for the axis of the northward flowing Antarctic Bottom Current in the South Atlantic. These velocities, considered high by some workers, met with some scepticism[3], but recent direct current measurements in similar current systems indicate velocities of the same magnitude[4]. In the South Atlantic, a good correlation is observed[5] between the occurrence of ripple and scour marks and the location of the Antarctic Bottom Current as determined by Wüst. Recently, Heezen, Hollister and Ruddiman[6] observed strong scour and other effects of bottom currents[6] on the continental rise and Blake-Bahama Outer Ridge[7]. They inferred[6] that geostrophic 'contour' currents in the deep sea are not only effective in transporting sediments, but constitute one of the principal agents in the shaping of the great sediment bodies of the continental margins[8]. These conclusions were based on an investigation of oriented bottom photographs, sediment cores and echograms. We have extended this study to the Antarctic Bottom Current and its effects on the Bermuda Rise.

In November 1965, on a cruise of the Duke University R.V. *Eastward*, a series of bottom photographs were taken between Cape Hatteras and Bermuda (Table 1 and Fig. 1). One of the stations on the continental rise beneath the Western Boundary Undercurrent[9,10] showed identical scour to that reported by Heezen, Hollister and Ruddiman[6] and, as predicted by them, the direction of current features was south-west, parallel to the contours. A photograph station from the lower continental rise showed smoothing without recognizable texture and the water was noticeably murky.

Table 1. BOTTOM PHOTOGRAPH STATIONS

Station No.	Location	Depth (m)	No. of photographs	Current magnitude and direction	Description of bottom as shown in photographs
3479	33 06 N. 70 04 W.	5,354	21	Moderate (no compass)	Sea pens bent over; various size mounds with tracks and trails
3480	32 48 N. 68 04 W.	5,145	26	Weak N.E.	Numerous track trails and various size mounds. Few manganese nodules
3482	32 32 N. 66 29 W.	4,986	16	Moderate N.E.	Numerous manganese nodules; several large tracks and various size mounds; sea pens strongly bent down-current
3488	31 58 N. 64 49 W.	4,148	18	Tranquil	Numerous small mounds with burrows and tracks
3500	33 02 N. 69 20 W.	5,355	20	Weak N.E.	Generally smooth bottom with many small mounds and a few manganese nodules
3501	33 00 N. 70 32 W.	5,278	16	Moderate N.E.	Smooth bottom with sponge, sea pens and crinoids bent down-current. Tracks and trails and few small mounds. 'Coca-Cola' bottle with light coating of sediment
3502	32 59 N. 71 35 W.	5,272	15	Tranquil	Very smooth bottom; few various sized mounds, burrows and tracks
3503	33 00 N. 72 33 W.	5,261	9	Very weak	Very murky water, soft bottom with large mounds
3507	33 32 N. 74 33 W.	4,617	14	Moderate to strong S.W.	Large sediment streamers; very soft bottom; large mounds with few tracks and faeces; water murky

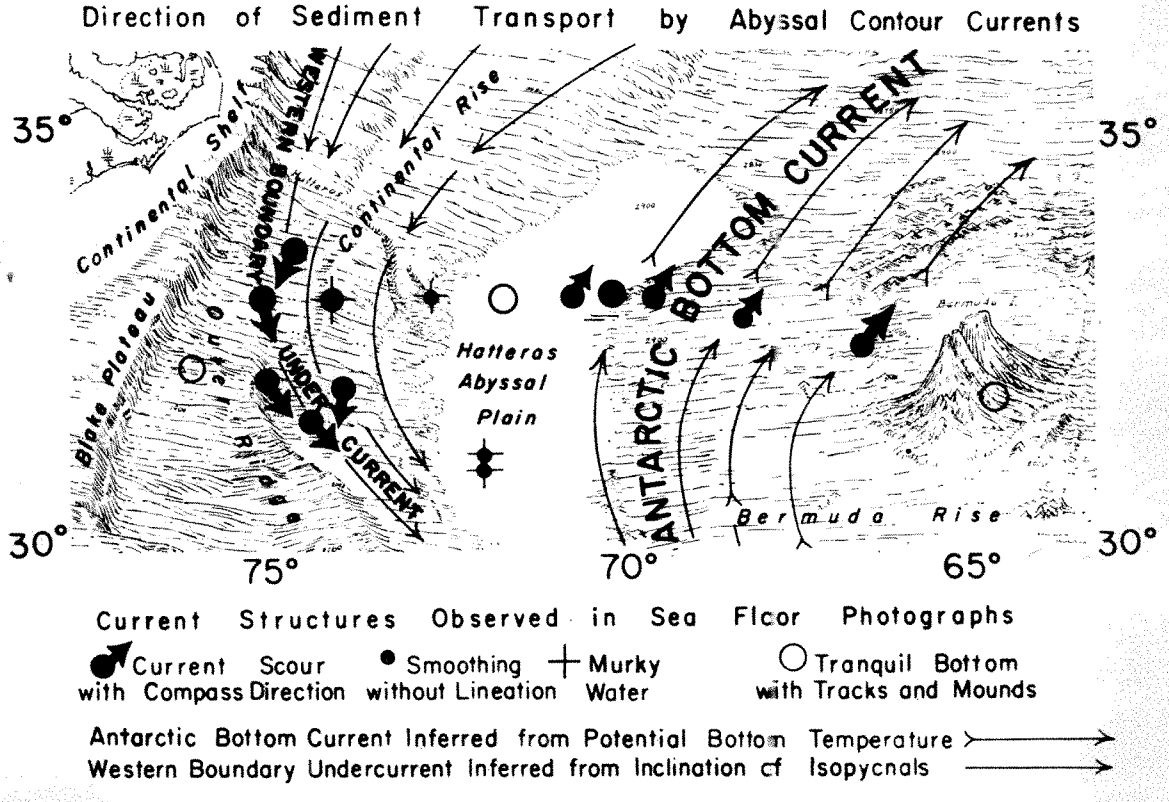

Fig. 1. Sediment transport in the western North Atlantic (ref. 6). Physiographic diagram (ref. 7)

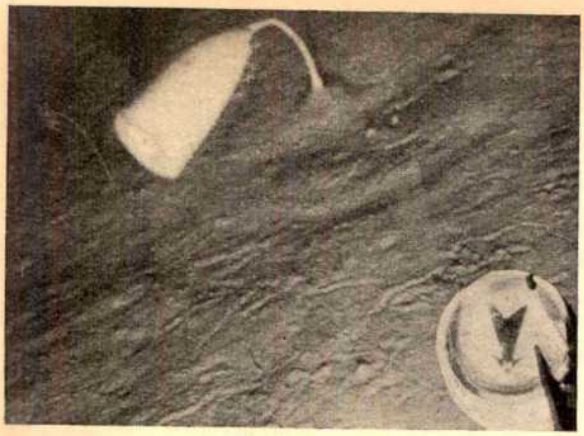

Fig. 2. Sponge and crinoid deflected to the north-east by the Antarctic Bottom Current. Compass 8 cm in diameter. Sponge has scribed a circular mark on the bottom from the north-west to the north-east suggesting that greater velocities sometimes bend the sponge to the sea floor and that the current varies in direction from N.W. to N.E. Station 3501

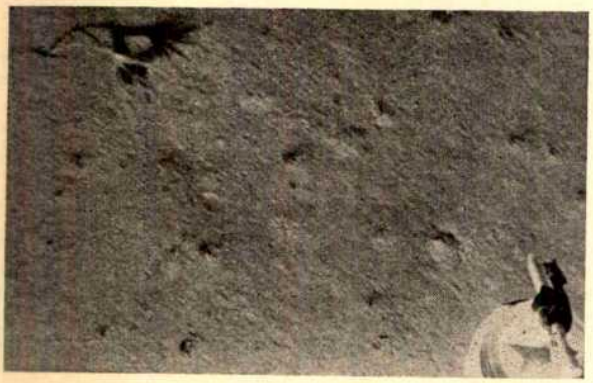

Fig. 3. The north-east fabric lineations result from the action of the Antarctic Bottom Current. Sea pen is strongly bent down-current. Note sediment streamers behind the dark-coloured manganese nodules. Station 3482

The Antarctic Bottom Current, as mapped by potential bottom temperature, is known to flow along the western flank of the Bermuda Rise[11,12]. The principal object of this series of photographic stations was to explore the effects of current on the bottom underneath this current. Five photograph stations on the bottom showed weaker current scour than was detected on the continental rise off Cape Hatteras, but the current was no less definite. The water appeared clearer and life was more abundant than observed under the muddy[13] Western Boundary Undercurrent. This latter fact led to the dramatic photographs of current-defected sponges and sea pens which were clearly bent with the current (Figs. 2 and 3). Manganese nodules were observed scattered over the bottom at several stations. Depositional tails of sediment on the lee side of these objects were often marked.

Evidence of the current was seen in the photographs taken on the eastern side of the Hatteras Abyssal Plain and on the Bermuda Rise. At all stations at which the pictures were compass-oriented, currents toward the north-east were indicated by the down-current deflexion of attached animals and the elongation of sediment streamers. These indicated a current parallel to the general contours of the area. The bottom photographs showed variations in the amount of scour and current evidence, but no quantitative estimates of current velocities could be made.

The sediments on the western Bermuda Rise lie near the boundary between red clay (more than 30 per cent carbonate) and globigerina ooze (less than 30 per cent carbonate)[14]. The actual range of carbonate contents is 25–35 per cent. The cores higher up on the Rise and those on the Bermuda Pedestal have a notably higher carbonate content. Most of the cores are thin-bedded. This is shown by variations of colours between manganese-rich and manganese-poor zones. Most of the dry cores split or break into beds along exceedingly thin laminae of very fine silt. The depth at which cold Pleistocene foraminifera give way to warm recent forms has been used to estimate abnormally high sedimentation rates for low carbonate pelagic lutites of the western Bermuda Rise. A post-glacial rate of approximately 3 cm/1,000 yr was inferred. As the penultimate interglacial was not recorded, late glacial rates could not be determined but were at least twice as high.

The Bermuda Rise is distinguished by smoothed low rolling hills. Seismic studies[16] indicate that its basement is covered by a relatively uniform mantle of nearly unstratified sediments 1–2 km thick.

The Antarctic Bottom Current may be a principal controlling factor determining the topography and sediment distribution of the Bermuda Rise. Its effects are less dramatic than the Western Boundary Undercurrent as it lacks a significant continental sediment source north of the equator. Its principal effects are in the redistribution of the slowly accumulating pelagic lutites. Since the Antarctic Bottom Current ceases to exist north of the Bermuda Rise, controlled deposition during its final dissipation may be responsible for the broad, thick, almost unstratified mantle of sediment which covers most of the Bermuda Rise.

A Major East-north-east Dislocation Zone in Central Malawi

WORK by the Geological Survey of Zambia[1,2] has revealed the presence of a number of major E.N.E.-trending transcurrent dislocation zones in the Pre-Cambrian rocks of that country. Such zones are characterized by intense

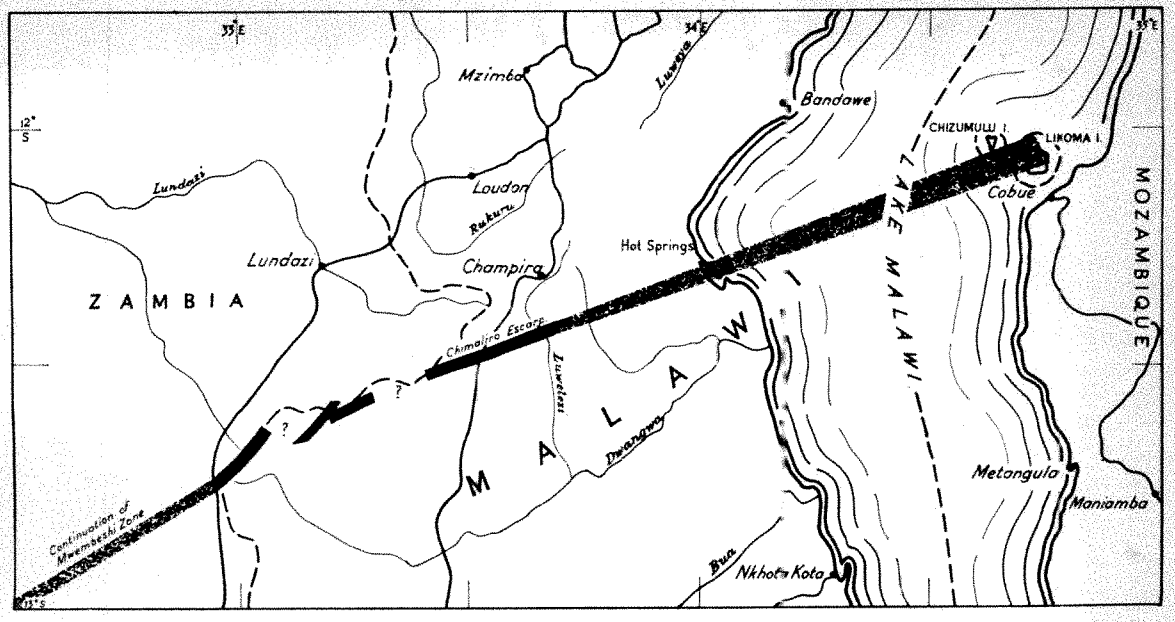

Fig. 1. The E.N.E. dislocation zone in central Malawi. The shaded bands represent probable extensions of the zone

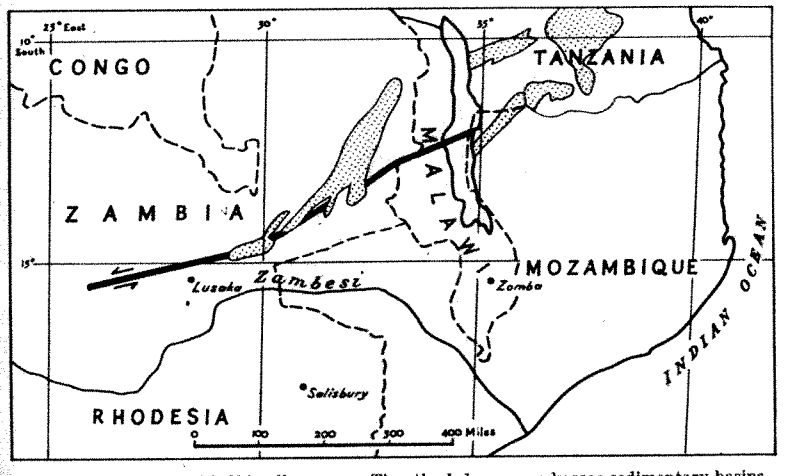

Fig. 2. The Mwembeshi–Chimaliro zone. The stippled areas are karroo sedimentary basins, partly fault-bounded

shearing, refoliation, blastomylonites and silicified gneisses. The best-defined is the Mwembeshi zone which can be traced discontinuously for some 500 miles eastwards from Mumbwa and is inferred[2] to enter Malawi at about the 12° 45′ S. parallel (Fig. 1).

Cooper's small-scale geological map of Malawi[3] shows a major fracture in the inferred position, separating rocks of Middle Pre-Cambrian age to the south from those of Upper Pre-Cambrian age to the north. Subsequent reconnaissance work has confirmed the existence of this fracture, and Chapusa[4] has traced a mile-wide band of mylonite for at least 20 miles along the crest of the Chimaliro escarpment (Fig. 1): the rocks to the north are high-grade psammitic gneisses containing garnet and sillimanite and, to the south, biotite-gneisses and phyllonites, contrasting lithologies but not of proved different ages. Peters[5] has mapped crushed quartzites, trending between N.E. and N.N.E., along the Zambia border between the 12° 45′ S. and 12° 30′ S. parallels and will have completed the mapping of the whole length of the fracture by the end of 1966.

Likoma and Chizumulu islands, which lie in Lake Malawi just off the Mozambique shore, have recently been shown to consist largely of graphic biotite–granite containing xenoliths of pelitic schist and (apparently) intruded by gabbros and microtonalites. The granites are strongly sheared along E.N.E. lines, a direction also followed by a number of major faults. The mafic rocks, although thermally altered, are not cataclastic and the relative age of the latest shearing movement is therefore apparent.

It is suggested that Likoma and Chizumulu lie on the eastern continuation of the Mwembeshi–Chimaliro dislocation zone, which thus trends E.N.E. for at least 600 miles from western Zambia to the eastern shores of Lake Malawi as shown in Fig. 2. Kazali hot springs on the western lake-shore also lie on this line.

Further to the east, in northern Mozambique and south-eastern Tanzania, no major dislocation is known, but the zone may be represented by the boundary faults of large karroo sedimentary basins in this area[6] and, still farther to the north-east, it may swing to follow the Tanzania 'fall-line'[7].

Although the Mwembeshi zone in Zambia follows an old line of weakness, its continuation in Malawi is represented, in part, by a mylonite band and a long escarpment and must be of comparatively recent age. Rejuvenation, possibly by normal faulting, seems likely. Further south, three other E.N.E. lines of weakness, apparently unrelated to those noted so far in Zambia, have been found to cross Malawi. One is followed by a line of infracrustal ring-complexes of Pre-Cambrian age[8] and the other two are associated with Lower Cretaceous plutonic activity[9,10].

The relationship of the Mwembeshi–Chimaliro zone to the rift faults bordering Lake Malawi merits some consideration. In Zambia the zone shows strong sinistral drag[1,2] but, if it is to be regarded as responsible for the apparent offset of the rift faults, movement in the opposite sense would be expected. An explanation of this may lie in the fact that the dislocation is caused by a transform fault as recently defined by Tuzo Wilson[11]. The parallel rift faults could have cut across an older E.N.E. line of weakness and the offset of the opposite sides is not a normal transcurrent displacement but due rather to a sinistral transform fracture as shown in Fig. 3. If this is so, it provides added support to Wilson's sugges-

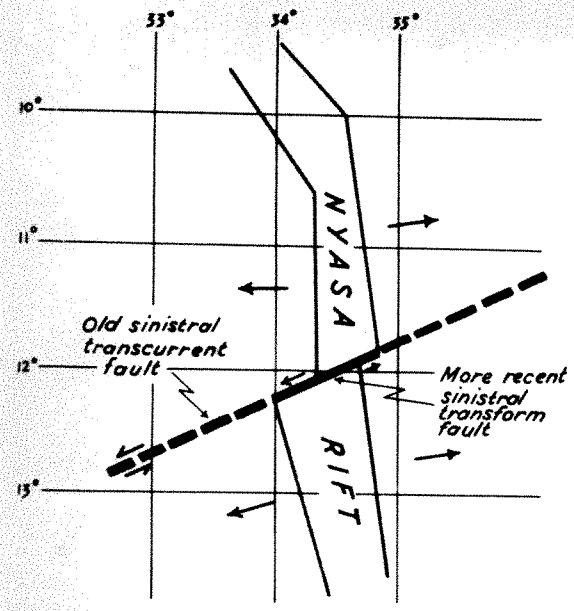

Fig. 3. Suggested relationship between the E.N.E. dislocation zone and the Nyasa rift

tion[11] that the African rift valleys are incipient mid-oceanic ridges.

Modification of the Model for Internal Structures in Graded Beds to include a Dune Division

AN important recent advance in our understanding of sedimentation in flysch basins is the discovery that the internal structures of most graded sandstones and limestones follow a fixed sequence. Proceeding upwards in a graded bed, the model-sequence described by Bouma[1] consists of five structures: (*A*) graded division; (*B*) lower division of horizontal lamination; (*C*) division of current ripple lamination, often deformed into convolute lamination; (*D*) upper division of horizontal lamination; (*E*) pelite division (Fig. 1). This sequence, or partial sequences with base, middle, and/or top truncation of one or more of the divisions, characterizes graded sandstones and limestones in many flysch basins in North America and Europe.

Walker[2] correlates these internal structures with bed configurations observed in flume experiments using medium sand (Simons and Richardson[3]; Table 1). The sequence of internal structures in graded beds reflects bed configurations that progressively develop as a current slows down.

The configuration of the dune bed that characterizes the upper part of the lower flow régime in flume studies

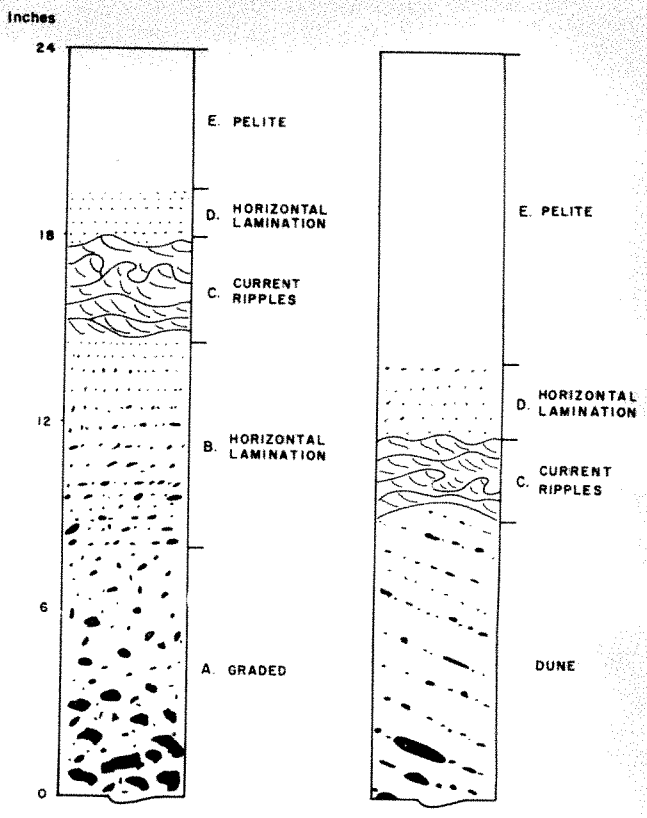

Fig. 1. Sequence of internal structures in graded sandstones and limestones. Sequence after Bouma (ref. 1) (left) and modification to include dune structure (right)

has not previously been reported for either graded sandstones or limestones. The dune structure does occur, however, for example in about 20 per cent of the graded limestones in a limestone flysch in the Upper Ordovician Whitehouse Formation in the Girvan District, southwest Ayrshire, Scotland. This limestone flysch section although faulted is at least 165 ft. thick, and consists of 65 per cent graded, sandy limestone beds, 8 per cent graded sandstones, 24 per cent silty micaceous green shale interbeds, and 3 per cent intraformational flat-pebble conglomerates (Table 2). The cross-bedded dunes in the limestones have wave-lengths of 15–20 ft. and amplitudes of 5–8 in. A *CDE* sequence of current ripples, horizontal lamination, and pelite overlies the dunes in each bed. The current ripples are occasionally deformed into convolute lamination whereas the dunes do not show deformed laminae. The *CDE* sequence is commonly slightly thicker than the basal dune structure.

The large wave forms in the Whitehouse graded limestones are dunes but not antidunes. In flume experiments[4],

Total	21	27	10	28	6	3	3	100	4	1	9	3	11	1	28	99	4

antidunes are structureless to crudely cross-laminated, with the cross-laminae inclined "upstream" at low (0°–10°) angles. The dunes in the Whitehouse limestones in contrast show distinct cross-lamination varying in dip from 5°–31°, averaging 17°. The cross-laminae are inclined uniformly down-current to the south-east in the same direction as the flutes on the limestone soles. Furthermore, the dunes in the limestones always occur directly below the current ripple division known to form in the lower flow régime.

The more complete sequences of internal structures tend to occur in the thicker graded limestones and sandstones of the Whitehouse Formation (Table 2). The dune-*CDE*, *ABCDE*, and *BCDE* sequences are common in beds that exceed 1 ft. in thickness. The graded division is commonly very thin, whereas the lower zone of horizontal lamination is thicker and simultaneously graded and laminated. In 1–2 in. beds, *C*, *CDE*, and *DE* sequences predominate. Flute casts occur sparingly on a few thicker and coarser limestones and sandstones implying, for each bed, that the same current both scoured the flutes and deposited the bed.

I have occasionally seen dune structures in graded sandstones in the Schlieren and Wäggital flysch sections of the External Prealps, Switzerland, and in the Lower Westphalian beds of North Devon. However, the reason for the common absence of a dune structure beneath the current ripple division in graded beds is not definitely established. Walker[2] suggests that either the water–sediment mixture lacks sufficient vertical thickness for dunes to form, or deposition was too rapid to allow time for dunes to develop. Perhaps a better lead for further investigation is that the dense, muddy current may inherently suppress development of dunes as suggested by flume experiments[5] in which, as more mud is added to sand, the dunes increase in wave-length and decrease in height.

The occurrence of a dune structure in the graded limestones of the Whitehouse Formation shows that such a structure should be incorporated below the current ripple division of the ideal model of a graded bed.

I thank Dr. E. K. Walton for directing my attention to the Girvan District. The University of Edinburgh provided office and laboratory facilities during my sabbatical leave (1964–65) from the University of Missouri. A grant from the University of Missouri Research Council paid for field expenses incurred. I also thank Dr. W. D. Keller for his help in preparing this communication.

Glauconite in the Subathu Beds (Eocene) of the Simla Hills of India

AUDEN[1] described the geology of the Pre-Tertiary and Tertiary formations of the Simla Hills and mentioned in passing the occurrence of glauconite in the Subathu beds. No detailed study of the mineral has so far been made. A petrographical investigation of the Subathu rocks of the type area (lat. 30° 58′ N., long. 77° E.), which is still in progress, has revealed that there are several glauconitic horizons in the Subathu Series. In the type area, the Subathus have thicknesses of about 2,500 ft. and are lithologically comprised of limestones, including coquinites, calcareous sandstones and shales which are carbonaceous at the base. Glauconite has so far been found to occur in the limestones and calcareous sandstones. These are fine to medium grained rocks, greyish in colour and at places traversed by secondary veins of calcite. Under the microscope they show variable amounts of clastic constituents—quartz, feldspars, rock fragments (limestones and quartzite) and accessories like glauconite, rutile, zircon, tourmaline, pyrite, chlorite, micas and iron oxides embedded in a calcareous matrix. Among the organic constituents, microfossils (tests of foraminifera) are quite abundant.

From an investigation of thin sections, two modes of occurrence of glauconite in the limestones and calcareous sandstones have been recognized:

(1) *Fillings of chambers of foraminiferal tests.* The chambers of the foraminiferal tests are filled with glauconite, although the number of chambers filled varies from shell to shell. It is clearly a case of replacement of the original calcium carbonate of the chambers by glauconite. In some cases the replaced substance (calcite) is seen recrystallized, forming clusters within the shell (Fig. 1). It is interesting to note that glauconite occurs in the chambers of the broken tests only. On the other hand, the chambers of the intact tests are either colourless or are filled with a brownish isotropic substance which contains inclusions of calcite and quartz. It differs from the glauconite seen in the same slide both in colour and in its behaviour under crossed nicols. The exact nature of this substance could not be determined, but it seems similar to the "clay fillings of foraminifera" of Takahashi (in ref. 2). It might be the starting material in the formation of glauconite as postulated by Takahashi[2]. After the rupture of the tests the clayey material presumably altered into glauconite by adsorption of elements like potassium, magnesium and iron from the marine environment.

(2) *In the matrix.* The glauconite of the matrix has an irregular outline and varies in size from 0·06 to 0·15 mm. A few grains are oblong to rounded and correspond in shape and size to the chambers of the foraminiferal tests; evidently they have come from the broken tests. Isolated grains of glauconite can also be seen in the fragments of limestone embedded in the matrix, indicating that glauconitization has taken place after deposition. Inclusions of calcite in the glauconite and pseudomorphs of glauconite after the rhombohedra of calcite are occasion-

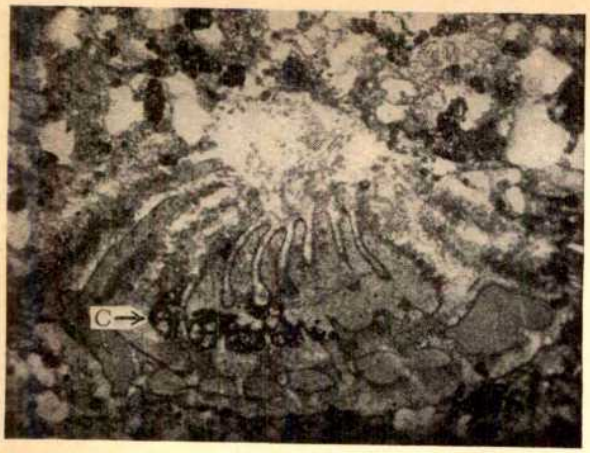

Fig. 1. Photomicrograph of calcareous sandstone showing chambers of a broken foraminiferal test filled with glauconite. The replaced carbonate has recrystallized as calcite (*C*), forming clusters within the test. Ordinary light. (×*c.* 50)

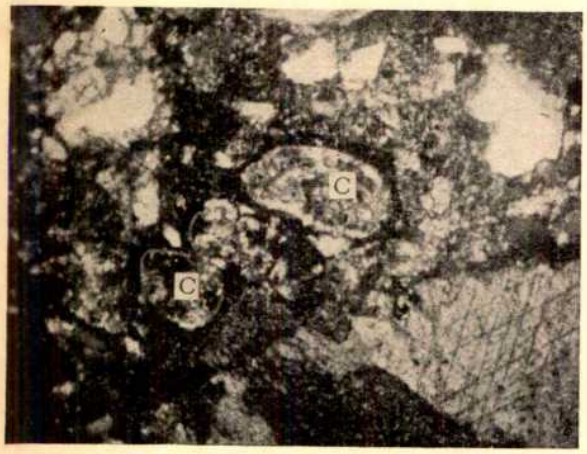

Fig. 2. Photomicrograph showing rings of glauconite round calcite (*C*) in the matrix of calcareous sandstone. Crossed nicols. (×*c.* 50)

ally seen. Continuous peripheral rings of glauconite around calcite are also observed (Fig. 2).

Glauconite forms less than 5 per cent by volume of the rocks as a whole. It has, therefore, not contributed significantly to the colour of the rocks.

As the mineral is soluble in hydrochloric acid, its separation from the matrix by treatment of the rock with hydrochloric acid was not undertaken. Optical investigations were made only in thin sections. Under the microscope the mineral has a yellow-green to light-green colour and is weakly pleochroic. A few grains show a tendency to limonitization. Cleavage is distinct in several grains. At times it is widely separated and in a few cases it is bent due to deformation. Extinction is nearly straight, but wavy extinction and aggregate polarization are frequently seen. Birefringence is low; grains are nearly isotropic. This may indicate a low content of iron in the mineral[3]. Detailed optical determinations are difficult due to the small size of the grains.

The following modes of origin have been ascribed to glauconite in sediments[4]:

Autochthonous glauconite: (*A*) of direct origin formed during sedimentation from colloidal matter, clays or alteration of biotite; (*B*) of replacement origin, involving matrix, microfossils, etc.

Allochthonous glauconite: of detrital origin.

The Subathu glauconite obviously originated by autochthonous replacement. A part of the glauconite of the matrix forming oblong to rounded grains may be regarded as allochthonous in the sense that it represents re-worked fillings of foraminifera. Evidence for replacement is found in the occurrence of inclusions of calcite in the glauconite grains, rings of glauconite around calcite and pseudomorphs of glauconite after calcite. Replacement has affected not only the foraminiferal chambers but also the matrix. In the case of the chambers, however, there is evidence that, in the first place, the original calcium carbonate was replaced by a brownish clayey material which subsequently altered into glauconite. The clayey material might be similar to the protoglauconite of Teodorovich (in ref. 5). Rhombohedra of calcite replaced by glauconite show that glauconite is younger than the diagenetic phase of early carbonate crystallization. Absence of glauconite from the veins of calcite indicates that the mineral was formed earlier than the veins.

Glauconite is an unusual mineral in sedimentary rocks and has gained much geological importance in recent years. The consensus of opinion is that a marine milieu is necessary for its formation in sedimentary rocks. This is borne out in the present case by the presence of glauconite in the Subathu beds of undoubted marine origin. Its occurrence in the calcareous sandstones and limestones and its association with foraminifera and pyrite lend support to the view that a slow rate of sedimentation and weakly oxidizing environmental conditions favour the formation of glauconite. It will be possible to throw light on the role of other factors like temperature, depth, salinity, etc., in its formation after the investigation of the Subathus is complete.

I thank Prof. I. C. Pande, of the Department of Geology, Panjab University, and Mr. Kedar Narain, State Geologist, Panjab, for a critical study of the manuscript. I also thank Mr. V. K. Gairola for assisting in the preparation of photomicrographs.

Composition of the Earth

RECENTLY, Birch[1] reported data on the density and composition of the mantle and core. He wrote: "The resulting densities in the lower mantle are found to be in good agreement with shock-wave measurements on rocks having FeO contents in the range $10 \pm 2\%$ by weight . . . except for iron oxide, the chemical composition of the mantle is indeterminate. The density of the outer core is lower than that of iron by about 10%".

Of the two major groups of chondritic meteorites, the olivine-bronzite and olivine-hypersthene chondrites, the average composition of the bronzite chondrites[2] is close to Birch's initial requirement. Table 1 shows an FeO content of 9·7 per cent, equivalent to 12·6 per cent FeO in the silicate fraction (76·04 per cent of the meteorite matter). The average composition of the hypersthene chondrites is 14·70 per cent FeO, equivalent to 17·0 per cent FeO in the silicate fraction, which is much beyond Birch's requirement of 10 ± 2 per cent FeO. It therefore seems reasonable to use the average composition of the bronzite chondrites to derive a composition for the mantle (plus crust), the core, and for the Earth as a whole.

Birch provided two solutions for the density distribution within the Earth, which for the present purpose differ only slightly. Using his solution II, we have a mantle plus crust making up 67·6 per cent and a core 32·4 per cent of the mass of the Earth. The calculation of the composition (Table 2) is based on the following assumptions: (1) the composition of mantle plus crust is the same

Table 1. AVERAGE COMPOSITION IN WEIGHT PERCENTAGES OF OLIVINE-BRONZITE CHONDRITES (REF. 2)

A		*B*	
SiO_2	36 57	O	33·24

P			0·10	0 10
K			0 07	0 07
Ti			0·05	0 05
	27·10	5 30	67·60	100 00

Mass of core equals 32 4 per cent mass of Earth, mass of mantle plus crust equals 67·6 per cent mass of Earth (ref. 1); core assumed to consist of nickel-iron of composition of average chondrite plus 5·3 per cent troilite, mantle and crust assumed to have composition of silicate material of average chondrite.

These assumptions are certainly oversimplifications. For example, all nickel is assumed to be in the core, whereas terrestrial olivine always contains nickel. (That from peridotite inclusions in basalt usually has 0·2–0·3 per cent nickel.) Some nickel is certainly combined in mantle silicates. Again, the assumption that all the iron sulphide is incorporated in the core is clearly at best an approximation, because some sulphide is certainly present in the mantle and crust. However, the incorporation of iron sulphide into the core rather neatly meets Birch's second requirement, that the density of the outer core is less than that of iron by about 10 per cent. If 27·1 per cent of nickel-iron, density 7·90, is mixed with 5·3 per cent troilite, density 4·80, the resulting mixture will have a density at zero pressure of 7·15, thereby meeting this requirement quite closely. This obviates the necessity of supposing silicon to be in the core, as has been suggested by Ringwood[3] and MacDonald and Knopoff[4]. A nickel-iron core with free silicon is also incompatible with a mantle containing appreciable amounts of FeO, if mantle and core are in chemical equilibrium.

A comparison of the elemental composition of the mantle plus crust with that of the crust reveals some interesting fractionations. The mass of the crust (the solid material above the Mohorovičić discontinuity) is $0{\cdot}024 \times 10^{27}$ g, that of the mantle $4{\cdot}016 \times 10^{27}$ g, so the mass of the crust is only 0·6 per cent that of the mantle. Table 3 shows that the major elements oxygen and silicon and the minor elements manganese and phosphorus show no marked fractionation between mantle and crust. In the crust magnesium is much diminished, relative to the mantle; chromium is also strongly diminished, as the average in the crust is about 0·02 per cent; iron, on the other hand, is only slightly less concentrated in the crust than in the mantle. Aluminium and potassium are strongly enriched in the crust, sodium and calcium to a lesser extent—in terms of phase composition the differentiation of crust from mantle has largely been the accumulation of feldspar in the crust. One notable feature, if the figures in Table 3 are reliable, is the remarkable enrichment of titanium in the crust, almost as great as that shown by potassium. There is no apparent geochemical reason for this enrichment; in fact, titanium might be expected to remain in the mantle as $FeTiO_3$ or in substitution in the pyroxene structure.

Table 3. ELEMENTAL COMPOSITION, IN WEIGHT PER CENT, OF (*A*) CORE, (*B*) MANTLE PLUS CRUST, (*C*) CRUST (*A* AND *B* FROM TABLE 2, *C* FROM REF. 5)

Green and Ringwood[6] recently discussed the composition of the mantle, and decided that it could probably best be represented by a dunite-basalt mixture, arguing that the partial melting of such a mixture would provide the basaltic magma so copiously injected into and through the Earth's crust, and leaving an upper mantle of dunitic composition. They decided the probable proportions of basalt and dunite were 1 : 3, and on this basis arrived at the composition of the mantle given in Table 4, where it is compared with the present estimate from chondritic composition.

Table 4. ESTIMATED COMPOSITION OF (*A*) MANTLE PLUS CRUST (THIS PAPER) AND (*B*) MANTLE (REF. 6)

	A	*B*
SiO_2	48 09	43·06
MgO	31 15	39·32
FeO	12·71	6·66
Fe_2O_3		1·66
Al_2O_3	3 02	3 99
CaO	2·32	2·65
Na_2O	1 13	0 61
Cr_2O_3	0 55	0 42
MnO	0 43	0·13
P_2O_5	0·34	0 08
K_2O	0·13	0·22
TiO_2	0·13	0·58
NiO		0 39
CoO		0 02
H_2O+		0·21
	100·00	100 00

When we consider that these two estimates have been made from completely different basic data, the general correspondence is quite remarkable. There are, however, numerous differences in detail. The calculated mineral composition is similar, with about 80 per cent olivine plus pyroxene and 13 per cent plagioclase, but the proportions of olivine and pyroxene differ in the two compositions, olivine greatly exceeding pyroxene in the Green–Ringwood composition as a result of their choosing dunite as a principal component. In their composition the total iron oxides correspond to 8·1 per cent FeO, just within the lower limit postulated by Birch, whereas the 12·71 per cent FeO in the present estimate slightly exceeds Birch's upper limit for FeO. The Green–Ringwood composition takes account of the nickel which is certainly present in the mantle, and also allows for a small amount of water, which is reasonable. With their figure for titania, the

titanium enrichment in the crust commented on previously becomes much less marked, although still significant. (It is possible that Poldervaart's estimate[5] of titanium in the Earth's crust is excessive.) The two estimates in Table 4 for the composition of the mantle show a marked degree of convergence, and suggest that the information now available does suffice to reach a fair approximation of the chemical composition of the inaccessible parts of our planet below the crust.

Independent Fission-fields of Caesium-134

THE radionuclide caesium-134 has a half-life of 2·1 years and is reported to exist in the Earth's atmosphere and biosphere including man[1]. The caesium-134 activities measured in air, foods and man are in the range of 0·1–2 per cent of the caesium-134 activity[2–4].

The process responsible for the formation of caesium-134 has been a subject for speculation, but no definite explanation seems to have been offered. One obvious suggestion is the creation of caesium-134 in fission nuclear bombs, but no yield has been reported for the production of caesium-134 in the fission of uranium or plutonium. Other processes in connexion with nuclear bomb devices are neutron capture in inert caesium-133, and neutron-induced reactions such as (n,p), (n,α) and multiple neutron capture in fission products or elements in the environment.

In the present investigation an attempt has been made to ascertain the magnitude of the possible direct fission-yield of caesium-134 by thermal neutron fission of uranium-235. In a reactor, caesium-134 is also produced by neutron activation of the stable fission-product caesium-133. In order to interpret the formation of caesium-134 in the light of these two reaction mechanisms, enriched uranium samples were irradiated for different periods of time. Thus with a short period of irradiation the caesium-134 activity should originate mainly from the fission process. Conversely, the caesium-134 activity should be ascribed mainly to the (n,γ) activation process of caesium-133 when long exposure to irradiation is used.

The accurate determination of low activities of caesium-134 together with strong activities of caesium-137 has previously been connected with certain difficulties, owing to an insufficient resolution of the photo-peaks of these two nuclides with a sodium-iodine crystal. However, recently developed germanium semiconductor detectors revealing a high degree of resolution allow accurate analysis of this kind.

Enriched 5–10 mg samples of uranium (90 per cent uranium-235) were irradiated in the *R2* reactor, Studsvik, with a thermal neutron flux of $\sim 2 \times 10^{13}$ n/cm² sec (fast flux: $\sim 4 \times 10^{12}$ n/cm² sec) for periods of 2·5 h, 1 day, 3 days, 8·8 days and 28·1 days.

The samples were dissolved in nitric acid (1 : 1) containing a few drops of hydrofluoric acid. Caesium carrier was added as well as a few mg of citric acid. The solution was evaporated to dryness and the residue dissolved in diluted hydrochloric acid. The solution was neutralized, and the bulk of the fission products were then separated from the caesium-134 and caesium-137 activities through sorption on an anion exchanger in the form of the hydroxide[6] and also by precipitation of barium sulphate.

The semiconductor detector was a lithium-drifted germanium diode with 2 mm depleted depth and 2·8 cm² area. The gamma-ray spectrum of the separated caesium sample (irradiated for 28·1 days) obtained by this detector, which was connected to a 512-channel pulse height analyser (Nuclear Data), is shown in Fig. 1. Small remaining activities, probably due to zirconium-95–niobium-95, are observed between the caesium-137 : 0·667 MeV peak and the caesium-134 : 0·797 + 0·802 MeV peak.

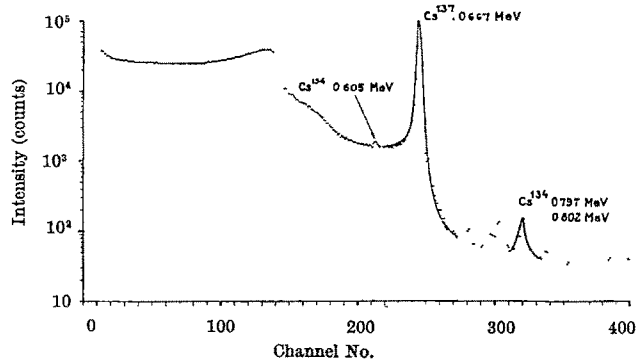

Fig. 1. Gamma-ray spectrum of caesium-134 and caesium-137 separated from the bulk of fission products, obtained by germanium semiconductor detector

Table 1 gives the measured caesium-134/caesium-137 disintegration rate ratio for the five samples investigated. Corrections have been made for differences in gamma-yields as well for the efficiencies of the full energy peaks corresponding to caesium-137 : 0·667 MeV and caesium-134 : 0·797 + 0·802 MeV. In the table are also given the caesium-134/caesium-137 ratios based on activation of casium-133, data from the compilation of Blomeke and Todd[6] being used in this connexion.

Table 1

Irradiation time	Caesium-134/caesium-137 disintegration rate ratio measured	Caesium-134/caesium-137 disintegration rate ratio calculated
2·5 h	$< 4 \times 10^{-4}$	$< 10^{-6}$
1 d	$< 4 \times 10^{-4}$	$< 10^{-5}$
3 d	$< 5 \times 10^{-4}$	$(8 \pm 2) \times 10^{-5}$
8·8 d	$(6 \pm 4) \times 10^{-4}$*	$(7 \pm 2) \times 10^{-4}$
28·1 d	$(35 \pm 9) \times 10^{-4}$*	$(50 \pm 10) \times 10^{-4}$

* Error is given as three times standard deviation.

In three samples irradiated for periods of 2·5 h, 1 day and 3 days respectively, caesium-134 could not be observed. Assuming the full energy peak of 0·797 + 0·802 MeV from this nuclide to be less than three times the standard deviation in the background in the peak region, an upper limit of 8×10^{-5} per cent is obtained for the thermal-fission yield of caesium-134.

For the samples irradiated for 8·8 and 28·1 days, respectively, the measured and calculated caesium-134/caesium-137 ratios were in reasonable agreement, as was expected.

The conclusion is that the direct formation of caesium-134 in fission is a process that may be ruled out as a possible explanation of the occurrence of caesium-134 in fallout. The caesium-134/caesium-137 disintegration rate ratio of 1·6 per cent measured in reindeer in the north of Sweden during March 1961[1] means that the yield of caesium-134 should have an order of magnitude of 10^{-2} per cent. This is a factor of more than one hundred times the upper limit determined in the present experiment.

This result is consistent with that reported by Baerg, Bartholomew and Betts[7], who found an upper limit of $1{\cdot}4 \times 10^{-5}$ per cent for the independent yield of caesium-134*m* in fission. The hypothesis of equal charge displacement indicates, moreover, that the yield of caesium-134 should be of the order of magnitude of 5×10^{-6} per cent[8]. This value is also consistent with the result obtained in the present experiment.

Other processes that might produce the caesium-134 found in fallout are now being investigated.

We thank Miss Lena Lindevall for skilful technical assistance.

THE SOLID STATE

Zinc Micas from Franklin Furnace, New Jersey

PLATY crystals of a dark mica occur in hancockite-bearing rocks from Franklin Furnace, New Jersey, and electron-probe analysis shows that the mica has high zinc (19·8 per cent) and manganese (12·5 per cent) oxide contents, corresponding to about 40 and 30 per cent respectively of the zinc and manganese end-members. So far as we are aware, no description of such a mineral has previously been published. This communication reports analytical, optical and X-ray data for two samples of the mica, one from the collection of the Department of Mineralogy and Petrology, Cambridge, the other from a hancockite–axinite rock presented by Prof. C. Frondel.

Table 1. ANALYTICAL DATA FOR TWO SAMPLES OF ZINC MICA

	1	2	3

1, Harvard mica, analysed by B. W. Evans; 2, Cambridge mica, analysed by R. G. J. Strens; 3, analysis of Harvard mica recast on basis of 24(O,OH,F). Total iron has been expressed as Fe_2O_3, total manganese as MnO.

The Cambridge sample (195037) contains large amounts of a yellow spandite garnet, with mica, franklinite, hancockite and axinite in moderate amounts, and some later chlorite. The Harvard sample was too small to section, but minerals identified in grain mounts and under the probe included major manganoan axinite and mica, with minor franklinite and hancockite.

Table 2. OPTICAL PROPERTIES OF ZINC MICA (HARVARD)

α	1 598	$(\gamma-\alpha)$	0·062
β	1 658	$a:z$	−6°
γ	1·660	$2V\alpha$	8°
Pleochroism	α	pale yellow	
	$\beta=\gamma$	light chestnut brown	
Absorption	(D)	$\gamma=\beta>\alpha$	
Dispersion		$r<v$, slight	

With the exception of lithium, which was determined by R. Allen using optical emission spectrography, and $(H_2O^+ + F)$, determined by heating a 75-mg sample of Harvard mica in air, all the constituents were determined on the electron probe, a systematic search being made for all elements with atomic numbers from 11 to 92. The following standards were used: biotite with average atomic number comparable with that of the zinc mica (magnesium, aluminium, silicon, iron), spessartine (manganese), sphalerite (zinc) and benitoite (titanium). Absorption, fluorescence and atomic number corrections were applied using procedures current in these laboratories. All iron has been stated as Fe_2O_3, in view of the presence of Mn_2O_3 in hancockite associated with the mica. A small fragment of the mica gave no red coloration when dissolved in a mixture of hydrofluoric and sulphuric acids, indicating that little if any Mn_2O_3 was present, and manganese has therefore been stated as MnO. The analysis in terms of oxides, and recast to 24(O,OH,F), is given in Table 1. The formula of a trioctahedral mica is readily apparent, though both alkalis and octahedral ions show a slight deficiency. Both samples have similar (MnO + ZnO) contents, but vary significantly in manganese : zinc ratio.

Table 3. UNIT CELL DIMENSIONS OF ZINC MICA (HARVARD)

a	5·34 Å	β	99 9°
b	9·312	V	505 5 Å^3
c	10 329	D_{calc}	3 30 g/cm^3

Polytype 1*M*

Single crystal photographs show the mica to be the 1 *M* polytype, in which respect it resembles manganophyllite rather than biotite. Powder photographs and diffractometer traces of the Harvard and Cambridge samples are identical, and the spacings and intensities are similar to those of manganophyllite.

The optical properties of the two samples are identical, presumably reflecting the similar (MnO + ZnO) contents, and indicating that manganese and zinc have similar effects on both optical properties (Table 2) and unit cell dimensions (Table 3).

Apparatus for Continuous Dielectric-medium Separation of Mineral Grains

THE usual methods for concentration of minerals from rocks by means of magnetic separation, heavy liquids, etc., do not always give satisfactory results. In some of these cases it is known that a good separation can be obtained using differences in the dielectric properties of minerals[1,2]. Briefly, the separation is based on the principle that, in a non-homogeneous electric field, particles with a higher dielectric constant than that of the medium in which they are immersed tend to migrate from a zone of low field strength into a zone of high field strength. Likewise, particles of lower dielectric constant than the medium are repelled into a zone of low field strength.

An apparatus has been developed at this laboratory for the continuous separation of mineral grains with different dielectric constants by applying a homogeneous electric field. In this case, the separation is based on the fact that a substance with a higher dielectric constant tends to replace a substance with a lower dielectric constant between the plates of a capacitor held at constant potential. Essentially, the apparatus consists of two parallel flat electrodes at a distance of 3 mm, the lower electrode consisting in part of a 0·75 mm sieve (see Fig. 1). Both electrodes are immersed in a liquid intermediate in dielectric constant between the minerals to be separated. The electrodes are connected to a 50 c/s a.c. source which can be varied continuously from 0 to 2,000 V. The source consists of a transformer with a variable transformer in the primary circuit. A 100 m.amp fuse is placed in the primary circuit and a resistance of 1 MΩ in the secondary circuit. The mixture of minerals is introduced between the electrodes by means of a vibrating feeder, and the electrodes are vibrated by a second vibrator. The intensity of vibration of both vibrators is variable.

If a liquid with an appropriate dielectric constant is chosen, minerals with a dielectric constant higher than the liquid form "strings" between the electrodes, while those

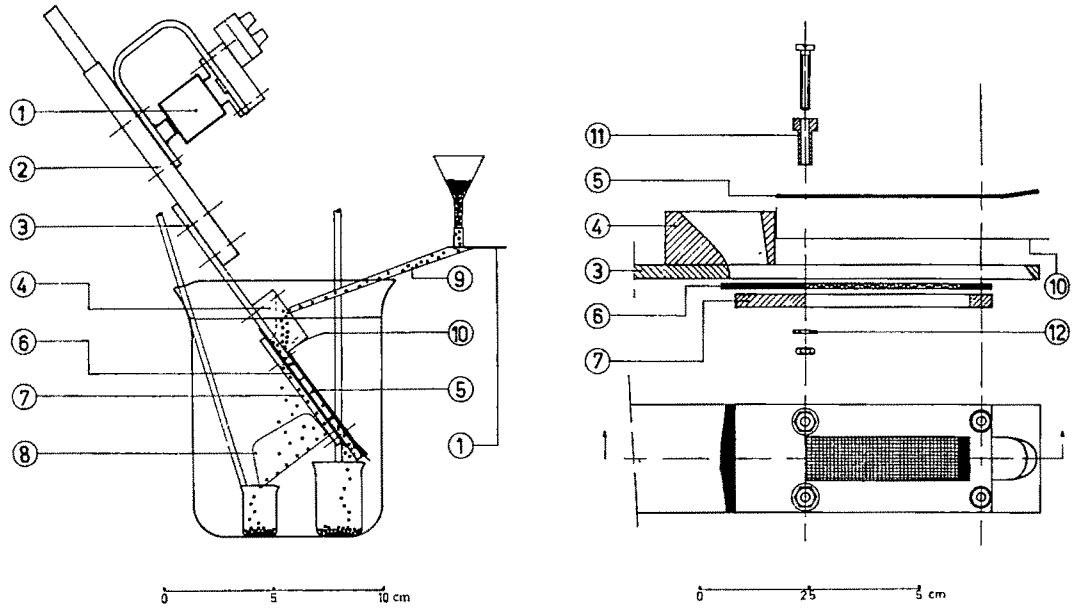

Fig. 1. Diagram of the separator. (1) Variable vibrator (the vibrator of the feeder is not shown), (2) vibrator-base (rigid polyvinyl chloride), (3) separator-body ('Perspex'), (4) separator-funnel ('Perspex'), (5) upper electrode (copper), (6) sieve-electrode (0·75 mm copper sieve partially soldered up), (7) clamping plate ('Perspex'), (8) chute ('Mylar'), (9) feeder-chute, (10) insulating-foil ('Mylar'), (11) bushing ('Teflon'), (12) ring ('Teflon')

with a lower dielectric constant fall through the sieve-electrode. Short-circuiting caused by conductive minerals is prevented by placing an insulating sheet of 'Mylar' underneath the upper electrode. The electrodes are given a forward slope so that the strings move towards the lower end of the electrodes, where they escape the electric field and consequently break down to loose particles.

The minerals falling through the sieve-electrode and those escaping the electric field at the lower end of the electrodes are collected in two small glass beakers placed in the liquid.

The apparatus was successfully applied to two mixtures of minerals difficult to separate by other methods: (1) nigerite, cassiterite and columbite-tantalite (from cassiterite-bearing albite pegmatites of Northern Portugal, supplied by Dr. C. Maijer).[3] and (2) biotite and astrophyllite (from riebeckite-gneisses in north-western Spain, kindly provided by P. Floor, Univ. Leyden), both containing minor amounts of other minerals. The former mixture contained roughly 65 per cent nigerite, 14 per cent cassiterite and 20 per cent columbite-tantalite with small amounts of tourmaline, zircon, chrysoberyl and gahnite. This mixture of minerals proved ideal for the development of the apparatus, because of their widely differing dielectric constants and the visual contrast between the red nigerite and the dark cassiterite and columbite-tantalite (the dielectric constant of nigerite seems to differ little from that of chloroform, as it is neither attracted nor repelled at 25° C and 50 c/s in a non-homogeneous electric field between two needle-shaped electrodes in this liquid. The dielectric constant of chloroform at 25° C and zero c/s is 4·7 according to Landolt-Börnstein. The dielectric constant of cassiterite at 10^{12} c/s is about 24 according to Landolt-Börnstein. According to Milner the dielectric constant of cassiterite is 50·0. Cassiterite is attracted in a non-homogeneous electric field at 25° C and 50 c/s in nitro-benzene with a dielectric constant of 34·67 at 25° C and zero c/s according to Landolt-Börnstein). Di-*n*-butyl-phthalate was chosen empirically as the dielectric medium (the dielectric constant of di-*n*-butyl-phthalate at 25° C and 10^7 c/s is 6·1 according to Landolt-Börnstein).

Nigerite, having a lower dielectric constant than the di-*n*-butyl-phthalate, fell through the sieve electrode; cassiterite, columbite-tantalite and intergrowths of nigerite with cassiterite and columbite-tantalite formed the strings. In this case two sieve fractions (+88–125μ and +125–250μ) yielded an almost pure nigerite concentrate after successive separations at 1,000 and 2,000 V. The first separation with the lower voltage gave a less pure concentrate but was required in order to prevent clogging of the space between the electrodes.

For the separation of a mixture of roughly 50 per cent biotite and 50 per cent astrophyllite with minor amounts of riebeckite, a mixture of butyl alcohol and kerosene was used in proportions of approximately 2:3, in order to create a suitable dielectric medium (the dielectric constant of butyl alcohol at 25° C and zero c/s is 17·7 according to Landolt-Börnstein. That of kerosene is 2·0 according to Milner). In this case, the astrophyllite and the riebeckite fell through the sieve-electrode, biotite forming the strings. Separation of this mixture of minerals proved to be less easy than that of the mixture of nigerite, cassiterite and columbite-tantalite, due to the apparent closeness of the dielectric constant of the minerals and to a gradual decrease of the dielectric constant of the liquid caused by evaporation of butyl alcohol. The index of refraction (1·4200 at 23° C) was used to control the composition. After repeated separations an almost pure biotite fraction was obtained. The astrophyllite fraction contained approximately 95 per cent astrophyllite.

We thank the staff and technicians of the Laboratory for Isotope Geology, in particular Dr. H. N. A. Priem for critically reading the manuscript, and Dr. E. H. Hebeda, Dr. N. A. I. M. Boelrijk and Mr. E. A. T. Verdurmen for helpful suggestions. This work forms part of the research programme of the "Stichting voor Isotopen-Geologisch Onderzoek", supported by the Netherlands Organization for the Advancement of Pure Research (Z.W.O.).

Paramagnetic Resonance Centres in Amethyst and Citrine Quartz

RECENT investigations[1,2] have shown that the colour and paramagnetic resonance (PMR) centres of violet amethyst quartz are related to one another in a rather complex way. This communication reports paramagnetic resonance lines in both amethyst and citrine (which is related to amethyst by heat treatment) not analysed previously, and the behaviour of these lines with heat treatment.

In all samples of natural citrine, a broad isotropic PMR line, about 100g in width, is observed (Fig. 1); its intensity is proportional to the depth of the yellow-brown colour. Both this line and the colour reach maximum intensity for annealing temperatures in the range 600°–700° C, and anneal out together at about 1,000° C. When natural amethyst is annealed at about 540° C, the violet areas turn yellow-brown; the appearance resembles that of citrine; and the broad isotropic PMR line appears. The colour of citrine has previously[3] been postulated as due to a yellow ferric compound (colloidal hydrous oxide); we suggest that the PMR line is due to Fe^{3+} in amorphous surroundings[4].

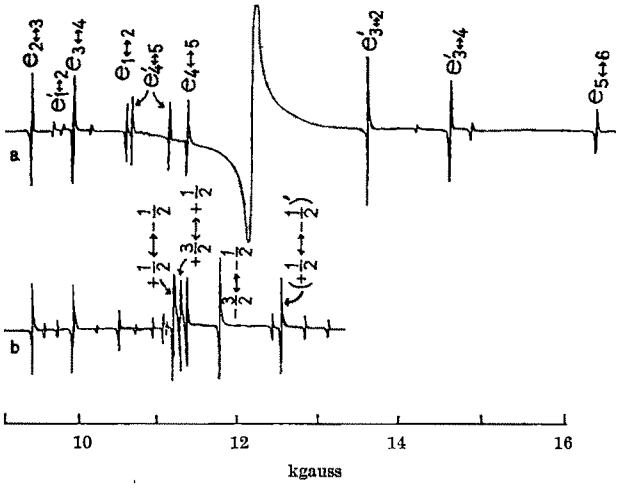

Fig. 1. 8 mm wave-length PMR spectra of (*a*) citrine, with $B\pi$ *a*-axis. The lines labelled *e* belong to the Fe^{3+} sites investigated by Hutton[1]; dashes denote sites with *x*-axes along the remaining *a*-axes. The energy levels have been numbered in order of increasing energy. (*b*) Amethyst; $B\pi$ *x*-axis of a site with $S = 3/2$

We have also observed that most samples of amethyst have three additional weakly populated sites for the Fe^{3+} centres previously analysed[1]. These sites have magnetic axes related to those of the strongly populated sites by a rotation of 60° about the *c*-axis. On heat-treatment to temperatures greater than the α- to β-phase transition temperature, the line strengths for the two sets of sites become nearly equal, due presumably to diffusion either of Fe^{3+} ions or the alkali precursors[1]. Typically, for one sample of amethyst, the ratio of the line intensities of the strong sites and the weak sites fell from 400 before annealing, to 100 after annealing at 500° C for 15 h, and to 1·3 after annealing at 700° C for 15 h.

We have also found two further PMR centres in amethyst, for which the magnetic axes are not related in any simple way to the crystallographic axes (Fig. 2). The observed three lines associated with these centres can be fitted with a spin-Hamiltonian

$$= g\beta\, B.S + 1/3\, D0_2^0 + E\, 0_2^2$$

where the 0_m^n are spin operators[5], $S = 3/2$, $g = 2{\cdot}004$, $D = 4{\cdot}24$ Gc/s, and $(E/D) = 0{\cdot}33$ (doublet zero-field splitting, 9·8 Gc/s). The *z*-axis for a site is defined as the axis making (E/D) a maximum. It was thought at first that these PMR lines might have been the stronger lines from a

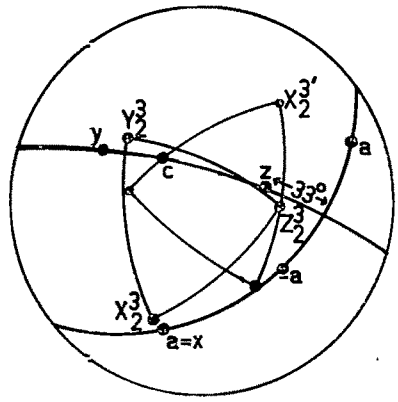

Fig. 2. Stereographic projection showing the relation of the magnetic axes of the Fe^{3+} centres (ref. 1) (*x*, *y*, *z*) and the centres with $S = 3/2$ (x'_2, etc.) to the crystallographic axes

centre with $S = 5'2$ (corresponding to Fe^{3+}); however, a careful search did not reveal the expected lines. No certain identification for this centre, which is not characteristic of all samples of amethyst, was possible.

Further work is planned on the correlations between changes in the optical absorption bands and changes in the PMR spectra produced by heat treatment.

Effect of Frequency on Texture-induced Ultrasonic Wave Birefringence in Metals

AN ultrasonic shear (transverse) wave entering a stressed solid body splits into two components travelling at slightly different velocities depending on the relevant elastic 'constants' which are slightly different along the two principal stress axes normal to the wave propagation direction. Thus the velocity difference between the two orthogonally polarized shear waves propagated normal to, and polarized parallel and perpendicular to, a principal stress axis should be stress dependent because of this effect of 'acousto-elasticity' or 'sonoelasticity'. This shear wave birefringence has been used in recent years to detect internal stresses in polycrystalline metallic specimens[1,2], but the interpretation of the results was difficult because the preferred grain orientation (texture) had identical effects to the internal stress. In the work described here, attempts were made with some success to separate the effects of stress and grain orientation on the ultrasonic shear wave birefringence.

Measurements have been made of the effect of ultrasonic wave frequency on the shear wave birefringence in a stainless steel sample. The stainless steel (*FV*-535) bar selected for the purpose has a relatively large amount of preferred orientation parallel to the major axis of the bar. The ultrasonic shear wave velocity differences (birefringence) are small, but can be measured accurately by electronic techniques. The shear waves were generated by lead zirconate titanate (*PZT*-5) crystals mounted in a pressure-coupled transducer[3] and propagated across the centre of the stainless steel bar held in a hydraulic press.

The changes in the difference of the transit times of the shear waves propagating normal to the axis, with polarization parallel to and perpendicular to the major axis, were measured by noting the shift in the zero crossing of a selected cycle of a selected echo, as the transducer was rotated from the first (parallel) to the second (perpendicular) position.

Measurements of the change in the time of transit of the shear waves in the frequency range 2–5 Mc/s were made in a stress-free condition and with an applied stress of 10,000 lb./in.^{2}. The results of the measurement are shown in Fig. 1, where the differences in transit time are plotted as a function of frequency. It can be seen that, within the limits of measuring precision, there is a linear relationship between shear wave birefringence due to grain orientation and frequency, and stress has equal effect at each frequency. Thus the birefringence due to stress alone is independent of frequency. The latter result conforms with the observations of Rollins[2] on aluminium at two frequencies, 2 and 5 Mc/s.

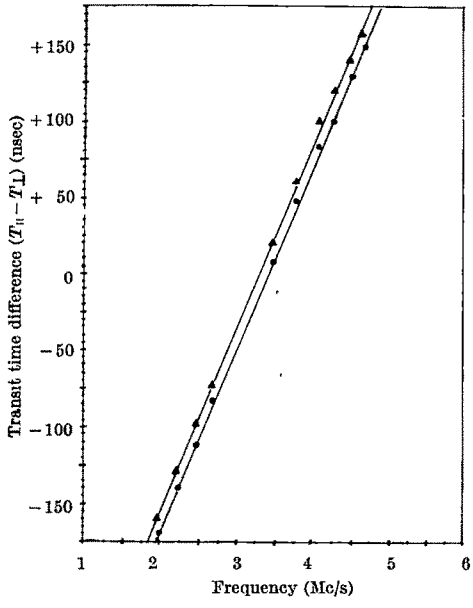

Fig. 1. Difference in time of transit plotted against frequency in stainless steel 1·25 in. thick. T_h[3], 19 μsec for "return trip". ●, Stress-free, ▲, stress of 10,000 lb./in.^{2}

The total fractional velocity difference $\left(\frac{\Delta V}{V}\right)_T$ could be represented by the expression

$$\left(\frac{\Delta V}{V}\right)_T = \left(\frac{\Delta V}{V}\right)_0 + \left(\frac{\Delta V}{V}\right)_S$$

where $\left(\frac{\Delta V}{V}\right)_0$ is the birefringence due to orientation alone, and $\left(\frac{\Delta V}{V}\right)_S$ is the birefringence due to stress alone. As calibration graphs could be plotted for the frequency dependence of $\left(\frac{\Delta V}{V}\right)_0$, as done in the present work, and stress dependence of $\left(\frac{\Delta V}{V}\right)_S$, already done by a number of workers, the above expression could be written as

$$\left(\frac{\Delta V}{V}\right)_T = \frac{\partial\left(\frac{\Delta V}{V}\right)_0}{\partial f} \cdot (f - f_0) + \frac{\partial\left(\frac{\Delta V}{V}\right)_S}{\partial S}(S - S_0)$$

where f_0 is the frequency at which the texture causes no birefringence, and the coefficient of $(f - f_0)$ is the constant slope of Fig. 1.

Thus:

$$S = \left[\left(\frac{\Delta V}{V}\right)_T - \frac{\partial\left(\frac{\Delta V}{V}\right)_0}{\partial f} \cdot (f - f_0)\right] \Big/ \frac{\partial\left(\frac{\Delta V}{V}\right)_S}{\partial S}$$

Effects similar to these were observed in samples of mild steel, aluminium and copper with different degrees of preferred orientation. A qualitative explanation of the results would be in terms of interaction of dislocations and ultrasonic vibrations. Future work will be done on samples having lesser degrees of texture and other types of steels and metals.

I thank Dr. D. I. Crecraft for suggesting this work, and Rolls-Royce, Ltd., for financing the project on residual stress analysis of which this work formed a part.

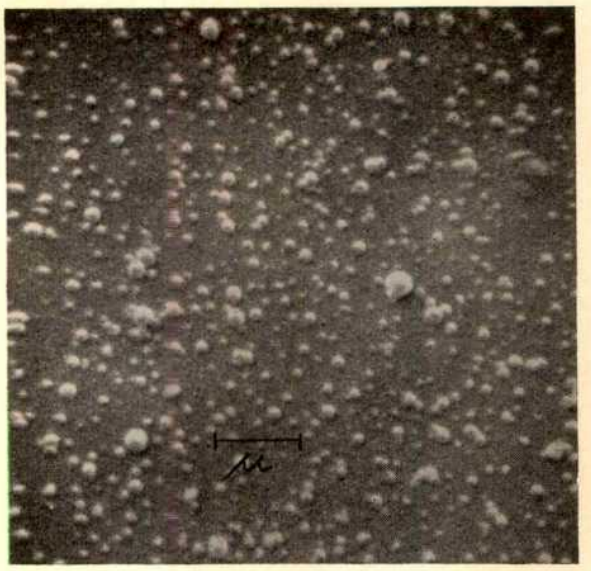
Three-dimensional View of Phase Separation in Glass Ceramics

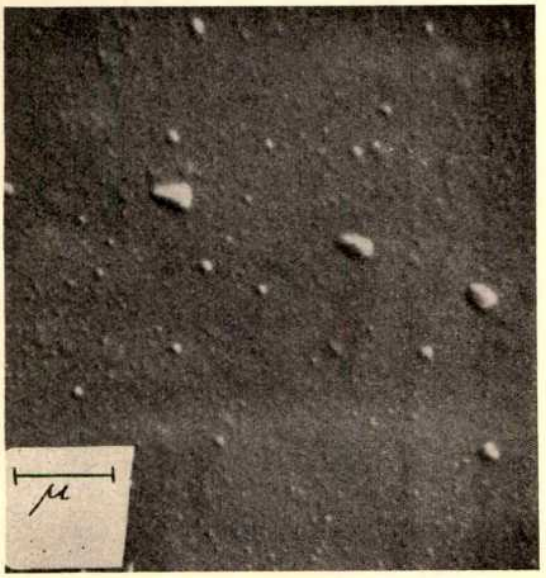
NUCLEATION and controlled crystallization of glass are now receiving considerable attention because of their importance in the manufacture of glass ceramics[1]. These materials are prepared by melting a glass batch containing a suitable nucleating agent and formed into a solid glass article by any conventional glass-making technique. The glass is later heat-treated in such a way that devitrification proceeds in a controlled manner and the article is converted into a glass-ceramic which is extremely fine-grained and nearly void-free.

As a result of extensive work[2,3] on this subject during the past decade, it is now believed that in many cases the first step in the formation of glass-ceramics is separation[4] of the melt into two metastable amorphous phases. Recently, Cahn and Charles[5] postulated that phase separation in glass can occur either by a nucleation and growth-mechanism or by spinodal decomposition.



In the past, electron microscope transmission pictures, taken on very finely powdered samples or on ultra-thin (200–600 Å) sections or replicas of freshly fractured surfaces (often suitably etched), formed the main basis of discussion on phase separation and nucleus formation in heat-treated glasses. Owing to the small depth of focus of the transmission electron microscope, however, these photographs only showed the three-dimensional nature of phase separation to a very limited extent. Information regarding the geometry and the distribution of the separated particles is, of course, vital if the operative mechanism in phase separation is to be successfully explained.

It has already been demonstrated[6] that even with very fine grained solids such as set Portland cement, the scanning electron microscope (Stereoscan) offers certain advantages in this respect. It was, therefore, thought worth while to undertake some exploratory investigations of the nucleation processes in glass-ceramics with this instrument.



Two complex aluminosilicate glasses prepared from an industrial waste material were examined. Fig. 1*a* is a photomicrograph of the freshly fractured surface of the original glass. The surface appears to be uniformly homogeneous at the magnification used. The white lines in the photograph are ridges caused by conchoidal fracture. In the preparation of the glass, small amounts of nucleating agents, titanium dioxide and chromic sesquioxide, were added to the melt. Figs. 1*b–e* are photographs of the freshly fractured surface of the glass heat-treated at 725° C (it is believed that this is the optimum nucleating

Fig. 1. Photomicrograph of a fractured surface of: *a*, the original glass; *b–e*, glass heat-treated at: 725° C for 15 min (*b*); 725° C for 30 min (*c*); 725° C for 1 h (*d*); 725° C for 2 h (*e*)

temperature) for varying periods of time. As can be seen in Fig. 1*b*, phase separation began after only 15 min heating, and even at this early stage the spherical particles generated show random distribution in size and position in the matrix, which suggests that nucleation and growth are operative mechanisms[6]. The progress of phase separation with time is clearly illustrated in Figs. 1*c–e*. The number of the spherical particles increased rapidly, and after heating for 1–2 h larger spheres are produced by coalescence of smaller ones. Thus the assumption that each small sphere acts as a nucleation centre for the formation of one crystal may not be valid. Another interesting feature of the advanced stage of phase separation appears to be the arrangement of small spheres into geometrical patterns which suggest some kind of dense packing before eventual fusion into larger spheres occurs.

An illustration of this dense packing can be seen in Fig. 2, which is a photomicrograph of the fracture surface of the second glass heat-treated at 725° C for 16 h. In this case, no external nucleating agent was added, but it is conceivable that minor components of the industrial waste material could have acted as such. The smallest

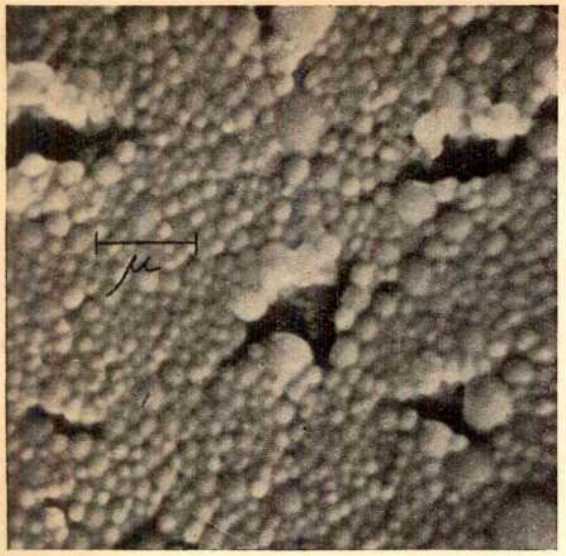

Fig. 2. Photomicrograph of a second glass heat-treated at 725° C for 16 h showing densely packed spherical particles resulting from phase separation

sphere discernible in Figs. 1 and 2 has an apparent diameter of about 600 Å. Without knowledge of the thickness of the metallic coating layer (in this instance gold–palladium alloy[6]), which is deposited on the specimen to facilitate thermal conduction and to prevent the specimen from becoming electrically charged, it is not possible to be more precise.

These preliminary results indicate that the scanning electron microscope may well provide a direct method of studying the nucleation mechanisms which operate in the production of glass-ceramics. Furthermore, it may now be possible to estimate the density of nuclei at different stages of heat-treatment with greater accuracy than heretofore and thereby to furnish useful data related to nucleation kinetics. Research into these aspects of glass devitrification is in progress.

The photographs were taken at the Research Laboratory of the Central Electricity Generating Board at Leatherhead, Surrey, and we thank Dr. C. Baker for his co-operation and assistance.

PHYSICS

Liquid Drop Model and Asymmetric Nuclear Fission

RYCE has recently directed attention[1] to the resemblance between curves representing the division of electrically charged liquid drops and mass yield curves for nuclear fission. He points out that the set of curves obtained from liquid drop considerations are similar to the fission yield

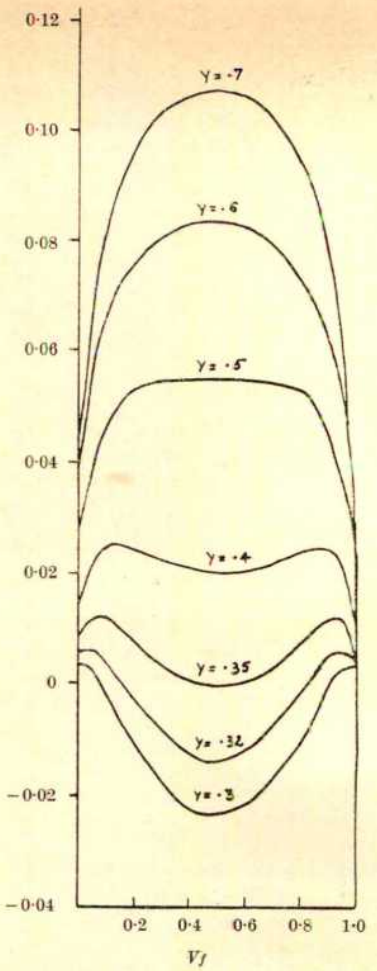

Fig. 1. Fractional energy change, E_f, plotted against the fractional volume change, V_f, for the division of charged drop where $Q \propto R^2$

curves (ref. 1, Fig. 1 left) obtained by Gibson[2] for fission of plutonium-239 induced by bombardment with deuterons of various energies. In the former, Ryce[1] has plotted the fractional energy change, E_f, versus the fractional volume change, V_f, for the division of a surface-charged drop. A V_f value of 0·5 corresponds to symmetric division. The parameter y is defined as:

$$y = \frac{Q^2}{16\pi R^3 T}$$

where Q is the charge on the drop, R the radius and T is the surface tension.

There is a superficial resemblance between the two sets of curves in a small range of values for y, and the relationship assumed seems to exist between the abscissae (drop volume and mass number) and the ordinates (excess energy and cross-section), although not necessarily linear in the entire energy range of the bombarding particle. We doubt whether the asymmetry of nuclear fission can be accounted for so simply by this model of surface-charged drop. Apart from the neglect of some vitally important variables which enter the mechanism of nuclear fission, we find that the similarity between the two sets of curves is misleading, as demonstrated in the following.

In the article by Ryce and Wyman[3] calculations were made for the volume-charged drops as well as for surface-charged drops. The corresponding curves for the volume-charged drop, an assumption more akin to a nucleus, bear no resemblance to Fig. 1 in Ryce's communication, in that they have no asymmetry whatsoever. It would be

incorrect to interpret this result giving much significance to the surface-charged drop model for nuclear fission, merely because of the similarity of the first two sets of curves in a very limited range. Calculations reveal that the form of the curves obtained does not depend in any way on how the charge density distribution is related to the radius. The only factor on which it does depend is how the total charge of a drop is related to the radius. The boundary conditions here considered are then $Q \propto R$ for the surface-charged drop and $Q \propto R^3$ for the volume-charged drop. For nuclei in the whole range of mass numbers, $Q \propto R^p$, where $2 \leqslant p \leqslant 3$. This conclusion is reached from a plot of Z and R for different nuclei (Z is the charge number and R the radius of the nucleus). In order to demonstrate that the similarity obtained with $Q \propto R$ is not truly significant, we obtained the corresponding set of curves for $Q \propto R^2$ shown in Fig. 1.

Our set of curves also corresponds to Ryce's Fig. 1, in a limited range of values of y between 0·32 and 0·60. Because a number of important variables have been ignored in this consideration, the match with nuclear fission yield cannot be expected to be better.

We believe that a liquid drop model with more simplifying assumptions and less stringent conditions than the Bohr and Wheeler[4] model is not likely to give results of much significance. Energy arising from deformation, activation energy, shell structure of nucleus, and nuclear binding energy should play a vital part in any calculation pertaining to nuclear fission.

We thank Frank Thomas, director of laboratories, for his help in the computational work involved.

Anomalous Reflectivity of Shock Waves

Experimental and theoretical data on the reflexion of light from shock waves have given conflicting results. Hornig *et al.*[1-3] have proposed that, because the shock front separates two regions of different density, Fresnel-type reflexions should occur. Further, they have demonstrated that such reflexions can be observed from shock fronts propagating in dry atmospheres in shock tubes. Mallory[4] has observed a reflexion of a ruby laser beam from the vicinity of a shock front produced by an explosive detonation in air. He found the intensity of the reflected light was three or four orders of magnitude greater than that which could be explained on the basis of a Fresnel reflexion. It seemed that a different phenomenon was giving rise to such reflexions.

There are obvious limitations to the amount of information which can be obtained from the type of experiment carried out on explosions in the atmosphere. (1) It is not possible to control the atmospheric environment. (2) Because of limited accuracy, it is not possible to determine the exact location of the reflecting region. Therefore, it is possible that the reflexion could have originated before, at, or behind the front. (3) The resolution of the equipment used in the explosive experiments is not such that any conclusion can be reached as to whether the reflexions came from a plane or from an extended volume. (4) It is not possible to determine the effect of using a laser instead of a broad-band incoherent source.

It appears that the best method of clarifying previous data is to examine shock waves propagating in shock tubes for reflexions other than those of the Fresnel type.

An experimental configuration was used which was similar to that described by Cowan and Hornig[1]. Illumination was by means of a helium–neon gas laser and the shock tube was fitted with a means for controlling the humidity. No reflexions were observed when the shock tube was operated in a normal manner (the sensitivity was insufficient to enable us to observe Fresnel reflexions). In one experiment the driver section of the shock tube was evacuated rather than pressurized. When the diaphragm was punctured, an expansion wave was initially propagated down the shock tube. Scattering was then observed when, and only when, the propagation media contained moisture. Furthermore, as the shock wave and the expansion wave reverberated in the tube owing to reflexions from the closed ends, the moisture alternately condensed and re-evaporated.

These results led us to examine the pressure history of the shock waves under investigation. When the shock tube was operated in its normal mode, the pressure never dropped below its ambient value. However, the pressure dropped to less than the ambient when the shock tube was operated so that scattering was observed. In fact, the periodic appearance of scattering could be directly correlated with the fall of pressure below ambient.

These experiments suggest that the reflexions observed from the explosively generated shock waves may also have been scattering from water droplets which are condensed in the expansion phase which follows the shock front. Hydrodynamic equations were used to calculate the lowest pressure and temperature reached during this expansion phase. This temperature was below the dew point at the time the explosive experiments were made. Furthermore, the intensity of the observed reflexions was consistent with the assumption that the phenomenon was scattering from particles with radii of 0·1–5 μm.

It was recently brought to our attention that the formation of clouds observed in nuclear explosions had been explained by a similar mechanism[5]. The effect has probably not been previously observed with small explosions because the region in which the "cloud" forms is close to the explosion and the droplets are quickly evaporated by absorbing heat from the fireball. Scattering from the droplets is insufficient to make them observable in shadowgraphic photographs of explosions.

Anomalously high reflectivities have also been reported from regions of the atmosphere. It has been suggested that these reflexions come from regions of clear air turbulence. Munick[6] has shown that it is not possible to detect Fresnel reflexions from the interface between regions of different density. However, it seems possible that air turbulence can produce conditions where local regions of the atmosphere expand adiabatically and are cooled to below the dew point. The condensed water droplets (or ice particles) may be responsible for the observed phenomenon.

This work was supported by a U.S. Air Force contract. We thank Dr. Henry Nagamatsu and others at the General Electric Research and Development Center for their assistance in the use of the linear shock tube facilities. We also thank Tom L. Sly for his technical assistance.

A Simple Device for the Scintillation Counting of Aqueous Solutions of Calcium-45 and other β-Emitting Isotopes

THE methods at present available for counting calcium-45 by conventional liquid scintillation techniques, such as those of Carr and Parsons[1], Sarnat and Jeffay[2] and Humphreys[3], make it possible to count large quantities of low specific activity calcium at efficiencies of 50 per cent or more. However, these methods are laborious and time-consuming because of the lengthy chemical processing required to produce a calcium salt which will dissolve in the toluene-based scintillator mixture. Methods involving the use of hyamine for the direct solution of tissues or aqueous solutions in toluene[4–6] are much quicker, but are only capable of counting very small quantities of calcium at lower efficiency; they are also subject to quenching errors. The use of plastic scintillator fibres or beads and anthracene crystals by Steinberg[7–9] made it possible to count directly colourless aqueous solutions of calcium-45; however, the efficiency, except with anthracene, was low, and the sample and scintillator materials could only be recovered with difficulty. Plastic scintillator systems consisting of a vial[10] and a flow cell[11] are capable of counting calcium-45 in aqueous solutions without any corrections for quenching, but their capacity is 1 ml. or less and their efficiency only of the order of 6 per cent.

In many applications it would be useful to be able to count calcium-45 directly in larger volumes of aqueous solutions without quenching corrections, even if at low efficiency. An apparatus designed for this purpose which has proved useful in this laboratory is shown in Fig. 1. It consists of an array of sixty plastic scintillator filaments (*NE* 102*A*, Nuclear Enterprises, Edinburgh), diameter 1 mm, length 4 cm, spaced at intervals of 2 mm between centres in a 'Perspex' disk. The filaments pierce the disk and their ends are ground and polished flush with its base. The disk is fitted to the bottom of a 'Perspex' cylinder, the whole forming a container of volume 8 ml. The "brush" counter, as we have called it, is suitable for counting aqueous, dilute acid or dilute alkali solutions of β-emitting isotopes in a liquid scintillation counter with a single photo-multiplier. If the filaments are covered with a depth of liquid greater than the range of the β-particles being counted, it is not necessary to measure the volume of solution counted; the count-rate is proportional to the specific activity of the solution. The counter has the following efficiencies:

Isotope	Efficiency (per cent)
Phosphorus-32	40
Calcium-45	2
Carbon-14	0·7

The background count rate is about 1/sec.

The counter can easily be modified to count samples larger than 8 ml. The Ekco *N664B* liquid-scintillation counter used in this laboratory would accommodate a similar counter of maximum volume 20 ml. It can also be modified in design to make its construction simpler if only high-energy β-emitting isotopes are being counted. For example, only six filaments in a brush counter are needed to count phosphorus-32 with an efficiency of 8 per cent.

The brush counter can be compared in its mode of operation and usefulness with the *M6H* Geiger–Müller liquid counting tube. The *M6H* counts phosphorus-32 with an efficiency of about 7 per cent and a background of 0·25/sec, but has zero efficiency for both calcium-45 and carbon-14. Using the simple $\frac{(\text{count})^2}{\text{background}}$ test, the brush counter could achieve comparable counting statistics for phosphorus-32 in an eighth of the time, and it is also useful for the weak β-emitting isotopes. The brush counter is therefore more versatile than the *M6H* tube and, compared with liquid scintillation techniques, it has the advantages of great simplicity of sample preparation and it is not necessary to make corrections for any quenching effects.

Changes in Loss Tangent of Polythene subjected to Partial Discharge

IN determining the resistance of materials to partial discharges, two distinct types of measurement tend to be used. In one, the time to breakdown is measured for film or sheet material mounted between rod/plane, needle/plane or hemisphere/plane electrodes. In the other, relatively large areas of sheet are subjected to discharge between plane/plane electrodes so that degradation after periods of exposure can be measured by following changes in conductivity, loss tangent, mechanical strength, etc. Because these properties change progressively with duration of exposure, the impression is being gained that the changes in the material which cause them are the same as those taking place in the breakdown process. This assumption leads to suggestions like that of Boeck[1] that impinging electrons become trapped in the material, forming a space charge and enhance the conductivity, the layer becoming ever deeper as fresh charge carriers are supplied.

We believe that, in general, the assumption is not justified, and that measurements on samples exposed to discharge between large plane electrodes can be misleading. Indeed, we suggest that the mechanisms leading to gross changes in measured conductivity are not the same as those leading to breakdown; the following experiment demonstrates this.

Films of low density polythene (MFI.7) 0·01 cm thick were subjected to discharges in a hemisphere/plane electrode system[2]. The gap between the hemisphere and upper film surface was 0·03 cm. Discharge was produced by applying 4 kV root mean square 500 c/s to the electrodes. On removing the film from the exposure rig after about 1 h and measuring the loss tangent at 500 c/s using plane/plane electrodes 1·75 cm in diameter, we found that the loss angle had indeed increased from its original value. The increase depended on the time of exposure, and at times just less than the time to breakdown (5–6 h) reached values in the range 0·04–0·5. During exposure to discharge an opaque white ring, 1·5 cm in diameter and 0·1 cm wide, was formed and by scanning the surface with a flat-ended rod electrode 0·3 cm in diameter, the high loss tangent was found to be confined to the material under the ring. Here the loss tangent reached 0·56; elsewhere, including the region immediately under the sphere, where breakdown invariably occurs, the loss tangent was less than 0·001 which was the limit of sensitivity. The ring was a surface deposit and could be wiped off with a dry cloth or better with ether, reducing the loss tangent to the original value. The deposit was not analysed, but oxalic acid and oxalates have been reported in similar deposits by other workers[3].

Interrupting the tests to wipe off the ring of deposit did not materially affect the time to breakdown. Breakdown frequently occurred soon after wiping when the loss tangent was low.

CHEMISTRY

A Lower Transition Point for Polymethyl Methacrylate at 30°–32° C

IN view of the use of polymethyl methacrylate (PMMA) for the production of surgical and dental prostheses, its properties at body temperature and those encountered in the mouth are of particular importance. Furthermore, the necessity for the incorporation of metal inserts and porcelain teeth makes its thermal properties of unusual interest. The thermal expansion of both commercial PMMA ('Perspex') and samples prepared by dental techniques was examined by means of a specially constructed dilatometer. Increase in length was recorded by means of a dial gauge reading to 0·0005 mm, and temperatures were measured at three points along 70 mm specimens by means of a Leeds and Northrup potentiometer. Specimens were arranged in a silica vessel which in later experiments was filled with water to determine the effect of water absorption on the thermal properties of PMMA. Increase in length was plotted against rise in temperature between 20° and 40° C. The resulting graphs showed a change in upward slope between 30°–32° C. The thermal properties were studied daily for periods up to 35 days with the specimens immersed in water and for similar periods with the same specimen drying out. Graphs prepared as before showed no alteration in the position at which an upward change in slope occurred, although the thermal expansion was greater for saturated specimens than for dry ones. Several second-order phase transition points have been recorded[1] for PMMA, but so far as we can ascertain, no reference to one in the temperature range of 30°–32° C has previously been reported.

It is considered that this observation is important in relation to the testing of the material for compliance with the appropriate standards, and it is suggested that the temperatures at which testing is now done may require review.

Molecular and Crystal Structure of a 5-Covalent Iron (III) Complex with Spin, $S=3/2$

THE magnetic properties of mononuclear compounds of tervalent iron (configuration $3d^5$) conform to the predictions of ligand field theory. Both high-spin $^6A_1$ (μ_{eff} = 5·9 Bohr magnetons (B.M.)) and low-spin $^2T_2$ (μ_{eff} = 2·3 B.M.) ground states are observed for complexes with octahedral microsymmetry. Quartet ground states (S = 3/2) are specifically excluded by the theory, so that the successful isolation of a new class of such compounds is of special interest.

We find that treatment with concentrated hydrohalic acids of a benzene solution of *tris*(dialkyldithiocarbamato)-iron (III) results in the immediate separation of crystalline compounds of the general type (Fe $(S_2C{\cdot}NR_2)_2X$), where X = Cl, Br, I and R = Me, Et, Pr^i, and Bu^{sec}. Typical of the series is the dark green crystalline compound, (Fe$(S_2C{\cdot}NEt_2)_2$Cl), which melts at 250°–255° C with decomposition and is monomeric in freezing nitrobenzene (at 1·5 × 10^{-2} M, molecular weight = 386 ± 10; calculated 388). The magnetic susceptibility of the powdered solid follows Curie's law between 130°–300° K with μ_{eff} = 3·98 B.M., close to the spin-only value of 3·88 B.M. for S = 3/2. In chloroform solution (3·1 × 10^{-2} M) at room temperature, the value 3·88 B.M. is obtained. The infra-red spectrum resembles that found for dithiocarbamates which are chelated to iron by way of two sulphur atoms. The iron-chlorine and iron-sulphur stretching modes occur at 309 and 353 cm^{-1}, and the high carbon–nitrogen stretching frequency in the region of 1,500 cm^{-1} suggests that delocalization of the π-cloud about the CS_2-group includes the adjoining nitrogen atom.

This evidence for a quartet ground state of an iron (III) compound is unambiguous, and to our knowledge is paralleled only by that for iron (III) phthalocyanine chloride as reported by Griffith[1]. A stereochemistry based on five-co-ordinated iron is suggested, but the data do not differentiate between the square pyramidal ($d_{x^2-y^2}\,sp^3$) and the trigonal bipyramidal ($d_{z^2}\,sp^3$) geometries. However, this ambiguity is resolved by X-ray methods using single crystals of the diethyl derivative.

The crystal data for the ethyl compound are as follows: $C_{10}H_{20}N_2S_4ClFe$, M = 387·8, monoclinic, a = 16·43, b = 9·42, c = 12·35 Å, β = 120·5°, U = 1713 Å^3, D_m = 1·52 (by flotation), Z = 4, D_c = 1·50 g cm^{-3}, space group $P2_1/c$, (C_{2h}^5; No. 14); co-radiation (unfiltered), single crystal oscillation and equi-inclination Weissenberg photographs, μ = 107 cm^{-1}.

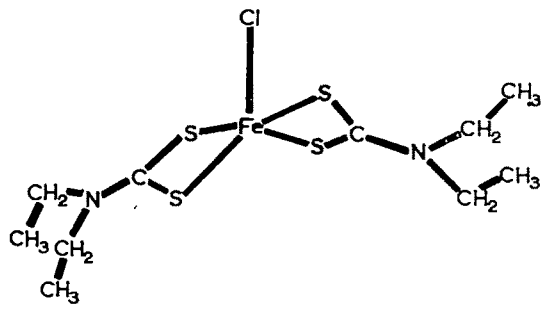

Fig. 1

The co-ordinates of the iron, sulphur, and chlorine atoms were obtained from a three-dimensional Patterson synthesis calculated using 1,440 independent reflexions. The carbon and nitrogen atoms were located in subsequent three-dimensional electron-density distributions. The structure is being refined by the method of least squares applying individual isotropic temperature factors. At present, the R-value, based on the observed reflexions only, is 0·16.

The structure consists of discrete molecules of composition $(Fe(S_2C{\cdot}NEt_3)_2Cl)$. Each molecule is separated from its neighbours at the normal van der Waals distances. The iron atoms are covalently bonded to four sulphur atoms and a chlorine atom at the corners of a somewhat distorted square pyramid (see Fig. 1). The Fe-Cl and the average Fe-S bond lengths of 2·27 Å and 2·32 Å, respectively, are normal. The four sulphur atoms are coplanar and the iron and chlorine atoms lie along a line which is almost exactly normal to this plane; the iron atom is, however, 0·63 Å above the plane. Apart from the terminal methyl groups, each of the ligand groups is planar and the iron atom is coplanar with both dithiocarbamate groups. The dihedral angle between the two planes through each of the groups is 50°.

Table 1

Compound	Distance of metal atom above basal plane	Ref.
$Co(S_2C{\cdot}NMe_2)_2NO$	0·54 Å	3
$Ni(5\text{-}Cl\text{-}SALen\text{-}NEt_2)_2$	0·36	4
$Co(OAsMePh_2)_4(ClO_4)_2$	0·32	5,6
$VO(acac)_2$	0·56	7
$Zn(disal)H_2O$	0·34	8
$Fe(S_2C{\cdot}NEt_2)_2Cl$	0·63	this work

There are no significant differences in the dimensions of the two independent ligand groups. The average carbon–nitrogen bond length of 1·36 Å is considerably shorter than the carbon–nitrogen single bond distance[2] of 1·472 Å. This together with the planarity of the ligand is consistent with the infra-red evidence indicating marked delocalization of the π-electrons in the co-ordinated dithiocarbamate group.

It is interesting to note that relatively few molecules with the tetragonal pyramidal stereochemistry for transition metal complexes have been established by X-ray methods. Nitroso(dimethyl-dithiocarbamato)cobalt provided the first example[3], and quite recently this novel stereochemistry has been reported for the N-β-diethylamineethyl-5-chlorosalicylaldimine derivatives of nickel (II) and cobalt (II)[4], as well as for monoperchloratotetrakis-(diphenylmethylarsine oxide) cobalt (II) perchlorate[5,6]. A dominant feature of these and related structures, based on a rectangular-based pyramid, is that the metal atom lies a considerable distance above the basal plane (see Table 1).

In addition to the mononuclear compounds listed in Table 1, many complexes of divalent copper have structures which involve dimeric or polymeric aggregates of approximately square pyramidal nature. Not infrequently the copper atom is found to lie above the basal plane.

It seems likely that this distortion from the regular geometry is a compromise between the condition of maximum σ-overlap with sulphur which requires the metal atom to lie in the planes of the chelating ligands and of steric expediency determined by the repulsive forces between the five ligands.

We thank Dr. A. D. Wadsley and Mr. W. F. Donovan, who undertook a preliminary investigation of the crystals and provided us with some of the intensity photographs. We also thank Dr. J. C. B. White for considerable help with the computations and for the use of his programmes.

Gas Chromatographic Determination of Non-linear Adsorption Isotherms at Low Concentrations

IN the course of an investigation of solid support effects in gas chromatography[1], it was necessary to determine the adsorption and distribution isotherms for a polar solute on an active support, both coated and uncoated. Because the concentrations of the sample in the gaseous phase were very low in this investigation, it was necessary to determine the isotherms for partial pressures in the range 0·5–10 mm.

There are three common methods for the gas chromatographic determination of adsorption isotherms. One involves the determination of the retention volume of a given concentration of sample by suddenly switching a mixture of sample and carrier gas into a clean column and measuring the retention volume of the sample front. This retention volume is equal to the quotient Q/C (ref. 2) Another method is the tracer pulse technique proposed by Helfferich[3]. However, the most common method is to calculate the isotherm from the shape of the diffuse rear boundary of an elution peak[4] or a desorption curve[5]. The mathematical basis for this technique was derived by Gluckauf[6].

Measurement of the Q/C values from sample fronts, or breakthrough curves, requires a separate experiment for each point on the isotherm, and one is restricted to rather large concentrations of solute. Rigid control of experimental conditions is required. For surface-active supports the most difficult experimental condition is the reproduction of the surface between runs.

The tracer pulse technique requires elaborate equipment for counting the radioactivity of the tagged sample and the method is restricted to samples that can be tagged with radioactive isotopes. In this case also, an experiment must be run for each point on the isotherm.

The saturation technique of Gluckauf has the advantages that the entire isotherm can be determined from a single experiment and it can be used at low concentrations. However, this method requires a knowledge of the area under the tailing portion of the chromatogram and thus cannot be used for small concentrations of polar solutes on an active support where the tailing portion of the curve approaches the baseline asymptotically.

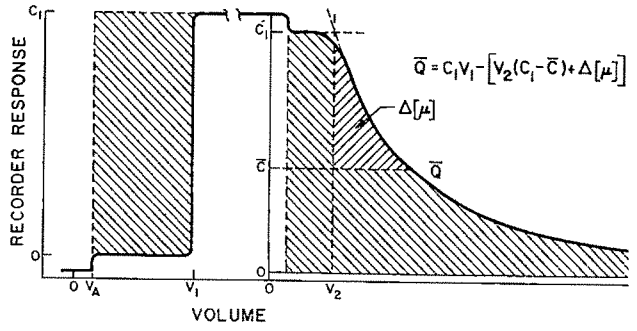

Fig. 1. Representative adsorption–desorption chromatogram

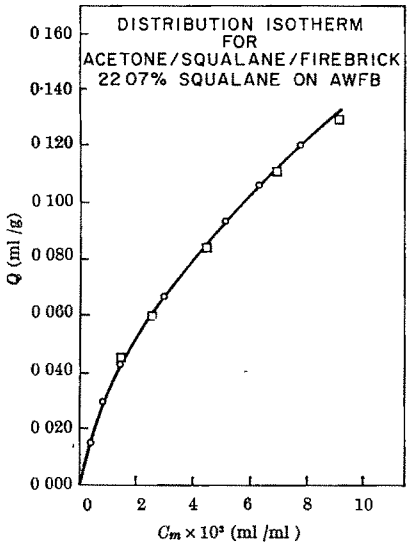

Fig. 2. Comparison of proposed isotherm calculation method with data obtained from break-through curves. ○, From $\bar{Q} = C_1V_1 - \{V_2(C_1 - \bar{C}) + \Delta[\mu]\}$; □, from $C_1V_1 = Q_1$

A combination of the sample front method and Gluckauf's method is the basis of the new technique. It has all the advantages of the Gluckauf method but does not require a measurement of the total area under the tailing portion of the chromatogram[7].

The small concentrations necessary for the sample in the carrier gas were obtained by bleeding a mixture of sample, nitrogen and carrier gas into the main carrier gas stream from a stainless steel tank with a capacity of about 1,000 in.³ (ref. 1). The nitrogen is used to give an air peak. This experimental arrangement is a distinct improvement over a liquid saturator or a constant-drive syringe. It gives better control at lower concentrations than either of these two arrangements and is much simpler.

The proposed method of determining the isotherm from an adsorption–desorption chromatogram is illustrated in Fig. 1. The retention volume of the sample front gives one point on the isotherm at the maximum concentration C_1. Mass balance requires that the area C_1V_1 be equal to the total area under the tailing portion of the desorption chromatogram. Measurement of C_1V_1 removes the necessity of measuring the area under the tail. Only the area designated as $\Delta[\mu]$ has to be measured, and this can be accomplished accurately down to the concentration at which the tail approaches the baseline.

From the initial saturation: $Q_1 = C_1V_1$ (1)

From the tailing portion[6]: $\bar{Q} = [\mu]_c + V_2\bar{C}$ (2)

By mass balance: $\bar{Q} = Q_1 - \Delta Q$ (3)

Where $\Delta Q = \Delta[\mu] + V_2\Delta C$ (4)

Substituting equations (1) and (4) into equation (3):

$$\bar{Q} = C_1V_1 - \{V_2(C_1 - \bar{C}) + \Delta[\mu]\} \quad (5)$$

Where C is the concentration of sample in the gas phase (ml./ml.), Q is the amount of sample adsorbed on the solid support (ml./g), V is the volume of carrier gas measured from the air peak (ml./g), $[\mu]_c$ is the area under the diffuse rear portion of the chromatogram (ml./g), and $\Delta[\mu]$ is the area under the curve as defined in Fig. 1 (ml./g).

Fig. 2 illustrates the distribution isotherm for acetone on a column of 20 per cent squalane coated on acid-washed firebrick. This isotherm was determined using equation (5). On the same graph a series of isotherm points determined using the sample front method alone are plotted to show the reliability of the new method.

This investigation was supported by a grant from the National Science Foundation. The gas chromatographic instrument used was obtained through a separate grant from the National Science Foundation.

Primary Organic Radical formed in the Radiolysis of Aliphatic Alcohols

In view of contemporary interest in the transient species formed in the radiolysis of aliphatic alcohols, it may be of value to consider the evidence regarding the nature of the primary organic radical-precursor of vic-glycol and possibly aldehyde

Recent investigations by the pulse radiolysis method[1,2] have shown the existence of solvated electrons in irradiated ethanol, and other studies[3–5] indicate that these electrons and hydrogen atoms are the precursors of scavengeable hydrogen; the relative yield being $G_H/G_{e^-alc.} \approx 2$. The primary reactions can be denoted as follows:

$$ROH \longrightarrow ROH^+ + e^- \quad (1)$$

$$ROH \longrightarrow ROH^* \quad (2)$$

$$ROH^+ + e^- \longrightarrow ROH^{\pm} \quad (3)$$

$$\left.\begin{matrix} ROH^* \\ ROH^{\pm} \end{matrix}\right\} \begin{matrix} \nearrow R\cdot O\cdot + H \\ \searrow R'\cdot OH + H \end{matrix} \quad (4), (5)$$

It is the purpose of this communication to assess the relative importance of processes (4) and (5). Although reactions involving the parent ion or the solvated electron can also lead to the formation of these radicals[3], it is proposed here to consider only those reactions involving the decomposition of electronically excited molecules (whether formed directly or as the result of the neutralization reaction).

Possibly the most direct identification of the radical precursor of vic-glycol has been accomplished by high-speed spectrophotometry following pulse radiolysis[1,2]. The identification made with liquid ethanol was the hydroxy-ethyl radical, but as the formation curve for the radical was not observed it could not be established whether this was, in fact, the primary radical produced.

The hydroxy-ethyl radical has also been considered to be the primary species in work[6] concerned with the isotopic composition of hydrogen produced in the radiolyses

of ethanol and various deutero-ethanols. The results have been interpreted in terms of the following reactions:

$$C_2H_5OH \longrightarrow CH_3.CH.OH + H \quad (6)$$

$$H + C_2H_5OH \longrightarrow C_2H_5.O. + H_2 \quad (7)$$

However, it will be shown that these results are capable of another interpretation.

Finally, electron spin resonance spectra of irradiated alcohol glasses also favour the acceptance of the hydroxyalkyl radical as the primary organic species. Early determinations[7] assigned the resonance in irradiated ethanol to the radical ion $C_2H_4^+$, but in later work[8] the hydroxy-ethyl radical has been preferred. Nevertheless, some doubt must exist as to whether the primary and subsequent events are the same in glasses as they are in liquids or vapours. In glassy[9] and gaseous[10] methanol irradiated with ultra-violet light, for example, there would seem to be considerable differences in the reaction mechanism.

The evidence in favour of the primary production of the α-hydroxyalkyl radical ($R'.OH$) having been considered, let us now consider the case for primary production of the alkoxyl radical ($R.O.$) arising from reaction (4).

Photochemical evidence in favour of reaction (4). Early works by Phibbs and Darwent[11] on the mercury sensitized photolysis of CH_3OD reported that the C—H bond was broken, but later work by Porter and Noyes[10] was interpreted to show that the initial cleavage was of the O—D bond. Recently, the mercury sensitized photolysis of CD_3OH and $(CD_3)_2$ Hg at low pressures in a flow system has shown[12] that $CD_3O.$ is formed and not CD_2OH. As the result of this work it has been suggested that the early work reporting C—H cleavage was confused by the reactivity of the methoxyl radical. This radical has been shown to abstract hydrogen readily from suitable donors and it is thought[13] that the energy of activation for reaction (8) will be quite small:

$$CH_3O. + CH_3OH \rightarrow CH_3OH + CH_2OH \quad (8)$$
$$(R.O + R.OH \rightarrow R.OH + R'OH)$$

The result is that in systems where reaction (8) can occur the hydroxymethyl radical will be observed. This interpretation has been confirmed[14] in the mercury-sensitized photolysis of ethanol in the presence of NO in which ethyl nitrite was found as a product.

Radiation chemical evidence in favour of reaction (4). In a recent investigation[15], the abstraction of hydrogen from ethanol by hydrogen atoms has been studied in the radiolysis of aqueous ethanol solutions. These investigations conclusively show that, although a small amount of abstraction from the β-position occurs, it is from the α-carbon atom that the major part of the hydrogen is abstracted with very little contribution from the hydroxyl hydrogen. In the light of this evidence, Burr's results[6] may be re-examined and interpreted to show primary cleavage of the O—H bond. This work clearly shows that the hydrogen atom formed in the original rupture and that which is later abstracted originate from different sites—for example, radiolysis of CH_3CH_2OD leads to the predomination of HD in the total hydrogen yield. Taking the data on abstraction into account, this is consistent with a mechanism involving reaction (4) as the primary step followed by reaction (9):

$$H + C_2H_5OH \rightarrow CH_3CHOH + H_2 \quad (9)$$

Furthermore, recent evidence[4] has shown that, although reaction (8) readily occurs in irradiated ethyl alcohol, suitable scavengers can compete successfully leading to the formation of products characteristic of the ethoxyl radical. Such a scavenger is carbon monoxide which, in addition to reducing the yield of 2–3 butane-diol, leads to the production of ethyl formate which can be explained on the basis of the following reactions:

$$CH_3.CH_2.O + CO \rightarrow CH_3.CH_2.O.CO \quad (10)$$

$$CH_3.CH_2.O.CO + CH_3CH_2OH \rightarrow CH_3CH_2OCHO + CH_3CHOH \quad (11)$$

General. A mechanism involving reaction (4) as the primary step followed by reactions (8) and (9) is compatible with the bond energies involved[16]. Hydrogen atoms and ethoxyl radicals should abstract hydrogen preferentially from the α-carbon (C—H 90 kcal/mole) rather than from the hydroxyl group (O—H 101 kcal/mole). The possibility of abstraction from the stronger bond would exist in the case of steric hindrances, but the structure of ethanol suggests that these will not play a part. With the hydrogen atom abstracting, the further possibility exists that it might be formed with excess kinetic energy (that is, a "hot" atom) and thus easily undergo the more difficult abstraction. The fact, however, that hydrogen is readily scavenged[3–5] indicates that this is largely untrue and that the existence of the major proportion of hydrogen atoms in a "hot" condition cannot be accepted.

It is believed that these arguments strongly indicate that in the vapour and liquid phases the electronically excited states, produced by irradiation of the alcohols with ultra-violet light or gamma-rays, decompose to yield the alkoxyl radical. This conclusion does not necessarily contradict data from electron spin resonance, which may not be applicable to liquid or gas phase irradiations. Nor is it contradictory to the pulse radiolysis experiments which can, in fact, be interpreted as verifying the reactivity of the ethoxyl radical. Furthermore, it is not the purpose of this communication to gainsay the role of the hydroxyalkyl radical as the immediate precursor of vic-glycol and possibly of aldehyde. In fact, chemical evidence, in the case of ethanol, is strongly in favour of these products being formed by dimerization or disproportionation of this radical.

$$2\,C_2H_4OH \longrightarrow \begin{matrix} CH_3CHOH \\ | \\ CH_3CHOH \end{matrix} \quad (12)$$

$$2\,C_2H_4OH \searrow CH_3CHO + C_2H_5OH \quad (13)$$

This, of course, is not sufficient evidence in favour of C_2H_4OH being formed initially; the same end-result would be obtained if reaction (12) were preceded by reactions (4) and (8). It does seem strange, however, that products attributable to CH_3CH_2O (for example, di-ethyl-peroxide) are not formed in appreciable yields in irradiated liquid ethanol. The major reason for this probably lies in the reactivity of ethoxyl so that reaction (4) competes very favourably with inter-radical reactions. Furthermore, it has been shown[17] that even under favourable conditions the reaction:

$$2CH_3O \longrightarrow CH_3OOCH_3 \quad (14)$$

is very slow and that disproportionation is favoured. Unfortunately, this disproportionation reaction (15) cannot be distinguished from that of hydroxyethyl radicals (13) as both lead to the formation of acetaldehyde:

$$2CH_3CH_2O \rightarrow CH_3CHO + C_2H_5OH \quad (15)$$

The presence of ethoxyl is, however, clearly shown in the reaction with carbon monoxide (10 and 11) and by the

fact that, in the irradiation of the pure liquid, small amounts of $CH_3OC_2H_5$ and $C_2H_5OC_2H_5$ are formed[4,18].

Adsorption of Caesium Tetraphenylborate from Aqueous Solutions on Glass, Polyethylene and Polytetrafluoroethylene

IT has previously been shown[1–4] that polyethylene (PE) and polytetrafluoroethylene (PTFE), unlike glass, do not act as cation exchangers. The adsorption of caesium from aqueous solutions on hydrophobic surfaces of PE and PTFE was negligible. This suggests a possible mechanism for such adsorption. PE and PTFE surfaces in aqueous solution acquire negative charge owing to adsorption of hydroxyl ions. These adsorbed ions may then attract caesium ions by electrostatic forces. In accordance with this hypothesis the adsorption values and the surface charge increase with *p*H. Comparing the adsorption values for caesium, thallium and silver ions on PE and PTFE[4] provides further evidence for a correlation between the adsorbability and the affinity of corresponding ions to hydroxyl groups.

In order to elucidate the mechanism of ion adsorption on hydrophobic non-ionogenic surfaces it was of interest to investigate the influence of other anions.

The present communication reports results of an investigation of the adsorption of caesium tetraphenylborate. It is known that the tetraphenylborate anion can selectively precipitate potassium, rubidium, ammonium, caesium, silver, tantalum and mercury ions in the presence of lithium, sodium and various di- and tri-valent ions[5]. Caesium can also be extracted selectively from aqueous solutions into organic solvents with high dielectric constants[6].

Let us now consider the data on the adsorption of caesium. The experiments were performed in 1 N sodium nitrate solution at varying concentrations of sodium tetraphenyl borate. The caesium concentration was approximately 1×10^{-9} M. The adsorption values were measured using caesium-137. The content of caesium-133 in the initial radioactive preparations was determined by the mass-spectrometric method of isotopic dilution[7]. Glass, PE and PTFE disks, 3 cm in diameter and 1 mm thick, were used to investigate the adsorption. The adsorption values were expressed as the ratio of caesium-137/cm^2 of adsorbing target to the activity of 1 ml. of solution under equilibrium conditions. The walls of glass vessels containing bathing solutions were first saturated with caesium ions until the radioactivity of the solution ceased to change. Adsorption on the targets scarcely affected the radioactivity of the solution, because the volumes of the bathing solutions were always much more than the surface capacity of all disks. The activity of the caesium-137 was measured by a scintillation spectrometer.

Table 1 shows that addition of sodium nitrate in the absence of sodium tetraphenyl borate strongly decreased the adsorption of caesium on all kinds of adsorbents. The adsorption coefficient (distribution coefficient) increases in the order: PTFE < PE < glass. The hydrophility of these adsorbents increases in the same direction[8]. As the wettability is determined primarily by the interaction of water hydroxyl ions with surface atomic groups, the caesium adsorption correlates with the wettability of the adsorbents. On glass, ion-exchange adsorption may also take place at low concentrations of sodium nitrate. The addition of sodium tetraphenylborate to the solution containing microquantities of caesium in 1 N sodium nitrate results in a strong increase of caesium adsorption and at the same time reverses the order of affinity of caesium ions to the surfaces investigated. The adsorption values are dependent on the concentration of tetraphenylborate and on adsorbability of this ion on surfaces of different natures.

Table 1. ADSORPTION OF CAESIUM FROM AQUEOUS SOLUTIONS OF SODIUM TETRAPHENYLBORATE ON GLASS, POLYETHYLENE AND POLYTETRAFLUOROETHYLENE SURFACES

Composition of the bathing solutions	Adsorption coefficients ($\times 10^4$) Glass	Polyethylene	Polytetrafluoroethylene
Water	22,400 ± 2,100	2,100 ± 200	2,000 ± 150
0 02 N sodium nitrate	610 ± 55	378 ± 25	187 ± 15
0 2 N sodium nitrate	60 ± 20	165 ± 30	73 ± 22
0 5 N sodium nitrate	20 ± 10	149 ± 25	25 ± 10
1·0 N sodium nitrate	—	53 ± 25	14 ± 8
1·0 N sodium nitrate + $2{\cdot}15 \times 10^{-3}$ N sodium tetraphenylborate	58 ± 10	240 ± 40	400 ± 55
+ $3{\cdot}40 \times 10^{-3}$ N sodium tetraphenylborate	258 ± 50	986 ± 124	1,570 ± 255
+ $4{\cdot}70 \times 10^{-3}$ N sodium tetraphenylborate	220 ± 35	3,300 ± 195	9,400 ± 750
+ $1{\cdot}1 \times 10^{-2}$ N sodium tetraphenylborate	630 ± 75	5,900 ± 450	25.400 ± 3,200
+ $2{\cdot}0 \times 10^{-2}$ N sodium tetraphenylborate	1,000 ± 160	9,000 ± 1,200	14,000 ± 2,500
+ $4{\cdot}8 \times 10^{-2}$ N sodium tetraphenylborate	490 ± 210	6,920 ± 1,100	27,500 ± 3,500
+ $1{\cdot}0 \times 10^{-1}$ N sodium tetraphenylborate	790 ± 145	32,800 ± 5,200	146,100 ± 21,000

At low concentrations of sodium tetraphenylborate, the major part of the caesium occurs in the ionic form[6]. The adsorption of caesium tetraphenylborate consists apparently of the following steps: (*a*) attraction of tetraphenylborate to surfaces by the van der Waals forces and/or hydrogen bonding; (*b*) selective attraction of the caesium ions by the adsorbed tetraphenylborate anions resulting in the formation of complexes on the given surface. With increasing concentrations of sodium tetraphenylborate considerable amounts of caesium can form the caesium tetraphenylborate complex directly in solution, with subsequent adsorption of this complex on the surfaces. As a result of adsorption, there are always non-charged complexes on the PE and PTFE surfaces because they have no ion-exchange groups in their structure[9]. Similar processes apparently occur on the glass in the case when the ion exchange adsorption is suppressed by high concentrations of sodium nitrate. In the range of caesium and sodium tetraphenylborate concentrations investigated, the solubility product of caesium tetraphenylborate was not reached[5]. Therefore the differences in adsorption values observed for glass, PE and PTFE are determined to a large extent by the molecular properties of the surfaces and adsorbate complexes. The ability of caesium tetraphenylborate

to selective adsorption was reported to occur at the oil/water interfaces[6].

Nomenclature of Metallic Elements

SINCE the discovery of the transuranic elements, a consistent method of naming the newly discovered metallic elements has been adopted. All these new elements have been given names ending in "-ium". It seems pertinent now that systematic changes are evident both in scientific nomenclature and in measuring units to discuss some aspects of the naming of metallic elements.

Of all the known metals, the following do not have names ending in "-ium":

Antimony	Lanthanum	Platinum
Bismuth	Lead	Silver
Cobalt	Manganese	Tantalum
Copper	Mercury	Tin
Gold	Molybdenum	Tungsten
Iron	Nickel	Zinc

Some effort is needed to introduce a revision of the names of the metallic elements in terms of the suitably consistent ending "-ium". Several degrees of consistency (least, moderate, and total) are now suggested.

Least consistency. In Europe, and perhaps in the United States, there is now little doubt that the name "niobium" is preferred to "columbium". Similarly, the name "aluminium" is accepted everywhere except in the United States. The names of the following four elements might be spelled with the "-ium" ending, introducing only the minimal amount of novelty: lanthanium; molybdenium; platinium; tantalium. These changes would dispose of the only four "-um" endings. Why this latter ending was first introduced when these four elements were discovered is not understood.

Moderate consistency. Several elements have consistent Latin names from which the chemical symbols for these elements are derived, an example being gold—Au(rium). However, the names of some metals are so well established that it would be almost pointless to change them, unless one insisted on total consistency. Examples of these are copper, silver, gold, iron, mercury, and tin. Nevertheless, it would seem a simple process to learn to accept the modified Latin names for antimony and lead, namely, "stibium" and "plumbium". For moderate consistency these changes plus the changes suggested for least consistency are desirable.

Total consistency. The following new names would be required if total consistency were mandatory:

Argentium	Cuprium	Nickelium
Aurium	Ferrium	Stannium
Bismuthium	Hydrargyrium	Tungstenium
Cobaltium	Manganium	Zincium

The element helium, a gas at normal temperature, has, with respect to the present discussion, an inconsistent ending to its name. The name "helion" is suggested as a replacement for its present confusing name.

It seems surprising that something so basic as the naming of the elements proceeded for so long without complete systematic care. In this scientific age it is time that the English-speaking scientists reached international agreement on the systematic naming of at least the metallic elements and perhaps all the chemical elements. This communication was written with the intention of provoking some thought and discussion on the subject.

This work was sponsored by the U.S. Atomic Energy Commission under contract with the Union Carbide Corporation.

BIOPHYSICS

Viscometry of Human Blood for Shear Rates of 0–100,000 sec^{-1}

Charm and Kurland[1] recently suggested that Casson's equation is applicable to the investigation of the viscosity of human blood for shear rates of 0–100,000 per sec.

I believe this statement to be only partially true. First, the physical interpretation given which supposes that the disaggregation of red cells proceeds in the range of rates of shear up to 100,000 per sec is quite wrong if the rates of shear refer to conditions in rotational viscometers. While some aggregates of red cells would be conceivable in axial flow in pipes (or vessels) even at very high rates of shear, the complete disaggregation[2] of red cells occurs already in the range of 10–60 sec^{-1} under conditions of homogeneous velocity gradient.

Any further decrease in the viscosity of blood, at progressively increasing rates of shear, is due not to the disaggregation of red cells, but to a gradual decrease in the internal viscosity of the red cell. Each red cell is in itself a complex rheological matter, both the interior and the membrane of the red cell forming a non-Newtonian system[3].

The viscosity of red cells, whether measured individually or as packed cells, will decrease progressively with increasing rates of shear. This phenomenon accounts for the experimental data and equations obtained by Charm and Kurland. In respect of rates of shear close to zero, from 0·001 to 10 per sec, the slope of the rheological curve (if correctly measured) is quite different from the one obtained at high rates of shear and is, indeed, due to the reversible aggregation of the red cells.

Although, by now, the statement of Charm and Kurland appears to be elaborated, other parameters unfortunately enter into the picture and make the final solution far from simple.

While the normal red cell (Hb AA), at its usual *p*H (about 7·4), will conform to the behaviour described, this is not necessarily true either for red cells containing abnormal haemoglobin or for red cells at abnormal (lower or higher) *p*H. A distinct possibility exists, although it has not yet been proved satisfactorily, that under some conditions the flowing blood might exhibit dilatant instead of thixotropic or shear-thinning properties.

In addition it is dangerous to deduce molecular or colloidal events from Casson's equation. The concept of critical yield stress might be especially misleading. It has been shown[4] that this concept has its place only as an arbitrary value. The critical yield stress is not a unique value of stress, but is a function of the time of application of this stress, and as such is represented by a curve if plotted as stress against time. A sensible (if arbitrary) concept of critical yield stress involves a state-

ment of time, for example, yield stress at 100 sec, or yield stress at 100 min.

Although it might be thought that in blood circulation the flow phenomena must be transient (one complete circulation of the red cell being of an order of 1 min), this is not so in pathological cases (various forms of stasis and intravascular clotting), and the time for one complete circulation might be quite appreciable in these cases.

Finally, I would like to suggest that rheological curves plotted on log–log scales have certain advantages in the micro-rheological[5] interpretation, as they make it relatively easy to account for the contributions of sub-phases or phases of blood to the blood viscosity.

Fission of Virus and Protein under Electron Bombardment

IT has been reported[1] that, provided threshold bombarding energies and current densities are achieved, it is possible to transfer metallic films deposited on an anode to a cathode *in vacuo* by electron bombardment (a thin film thermionic emitter was used as a detector). The mechanism of release can be considered to arise from (*a*) an energy conversion yielding thermal evaporation over areas of atomic dimensions of the surface layer, or (*b*) an indirect one involving ionization *in situ* and the breaking of metallic bonds of a fraction of the surface atoms.

Recently, a gas-contaminated fine tungsten point was used to detect singly charged positive gas ions between a cathode and an anode[2]; about 400 impacts per sec were recorded at a pressure of 10^{-5} mm mercury. This work has now been extended to detect the fission into complex atom groups and single atoms as a result of bombarding with electrons, virus and protein material placed on the anode. *Pseudomonas* bacteriophage was used at a concentration of 7×10^7 virus particles per c.c. There is no *a priori* reason why the mechanism of detachment in an insulator should differ from that in a metal if the impact is a 'correct' one. To reduce impacts arising from any residual gas, the anode system consisted of a cylindrical box of copper–nickel 20 mm in diameter, 15 mm long and with a central 3-mm hole through which a tuft of four thoriated tungsten wires projected for a distance of 3 mm; these were insulated from the box, and faced a finely etched thoriated tungsten point detector, 1 cm away.

The method used in the experiment was to connect the box and tufts together so as to establish a 'threshold' voltage for gas ionization; if the anode was made 20 per cent negative to the tufts, it reduced the number of single impacts arising from any gas to very small value—something in the order of 20 per sec. An inspection of some 5,000 oscillograph traces showed the usual recovery time and form of the current variations—about 1 msec and 50 per cent, respectively; examples are shown in Figs. 1*a* and *b*. When the tufts were coated with the bacteriophage (about 100 virus particles), there was a time lag of 1–3 min before impacts were detected at the 'threshold', but a steady increase of single impacts up to 300 per sec soon became apparent. This effect is shown in Fig. 2*a* and indicates that the bonds in the virus and protein material on the tufts had been broken. In actual fact, the anode competes with the detector for the disintegration products and, when bombarded, gives a curve such as is

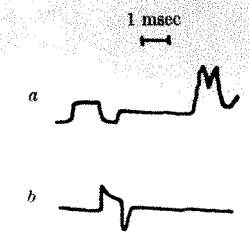

Fig. 1. Single impulses arising owing to the presence of gaseous ions *a*, Anode; *b*, tufts

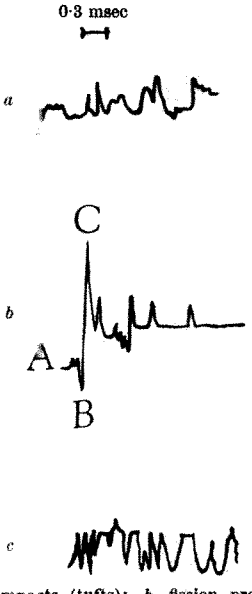

Fig. 2. *a*, Single impacts (tufts); *b*, fission products; *c*, successive impacts

shown in Fig. 2*b*, where the current variation is 500 per cent. The extremely small reaction time coupled with excessive variations in current are never recorded with gaseous ions, but it is probable that they arise from the fission of the virus and protein material. A possible interpretation of curve 1*b* is that the initial portion, *A*–*B*, arises through the cutting off of the beam as the particles proceed towards the detector; this region thus represents the transit time. Subsequent disturbance on the surface produces the 500 per cent current increase, *B*–*C*. On the basis that the average recovery time varies inversely as the square root of the mass, the portion *ABC* represents a fission product of about 400 Å diameter. Subsequent peaks indicate unusual complexes with masses of 40–140 times that of the oxygen atom. The striking succession of single ions which originate at a localized point, shown in Fig. 2*c*, nearly always occur in spasmodic bursts at some stage of the bombardment; this results in the great activity at the detector.

The layer on the tufts is polarized by the field, and may be some 1000 Å thick. This is easily penetrated by the 3–4-kV electrons; the secondary electrons should have sufficient energy to escape, but they are prevented from doing so because there are no fields in the right direction. Thus such electrons pass on their energy to the lattice, and help in breaking the bonds of some of the atoms penetrated. An approximate calculation shows that each primary electron releases $1/10^{24}$ of the atoms in the coating.

I thank Dr. Bell of the Department of Microbiology for supplying me with the solution of *Pseudomonas* bacteriophage for these experiments.

PHYSIOLOGY

Effects of Cold Stress on Serum Protein Fractions of the Prairie Meadow Mouse

THE reaction of an animal to cold stress varies with the species and with the degree of stress imposed on the animal. Shields, Platner and Neubeiser[1] have shown that the albino laboratory rat reacts to a cold stress (4·0° ± 2° C for 20 days) with a marked decrease in serum albumin. They regarded catabolism of albumin as the prime factor responsible for its fall in serum.

The present investigation was undertaken to test the effects of cold stress on the distribution of serum protein fractions of a wild species of rodent, the prairie meadow mouse, *Microtus ochrogaster*, and compare its response with that of the rat. The meadow mouse, common throughout Missouri, was obtained from a stock raised in the laboratory. These animals do well in captivity and can be obtained in large numbers.

Twenty-four virgin females of the same age were divided into two equal groups. The control group was held at 22° C room temperature while the experimental group was placed in a cold room with a temperature of 5° C ± 1·5° C. Both rooms were on a timed 12-h light cycle. Each mouse was individually caged with water and feed *ad libitum*. The food was 'Purina' laboratory rat chow, identical to that used by Shields *et al.*[1] in their experiments on the rat.

After 20 days, the mice were bled by heart puncture. The blood was allowed to clot and the serum obtained was stripped on electrophoresis paper and migrated in the 'Beckman/Spinco Model *R*' cell with barbiturate (Veronal) buffer, *p*H 8·6, ionic strength 0·075. The paper strips were stained with bromophenol blue dye and scanned on the 'Beckman/Spinco Analytrol' equipped with the *B*-3 cam. Total protein was measured with a Goldberg refractometer (American Optical Co.).

Table 1. MEAN VALUES AS PERCENTAGE OF SERUM PROTEIN FRACTIONS OF MICE BEFORE AND AFTER EXPOSURE TO COLD

	Controls	Cold-exposed
Weight change (g)	+3·7 ± 0·78 (12)	+2·8 ± 0·69 (12)
Total protein (g)	5·2 ± 0·53 (7)	5·2 ± 0·18 (8)
Albumin	67·1 ± 1·50 (11)	70·7 ± 0·57* (10)
α-1 globulin	4·6 ± 0·47 (11)	4·9 ± 0·29 (10)
α-2 globulin	10·2 ± 0·30 (11)	9·0 ± 0·63 (10)
β globulin	15·0 ± 1·03 (11)	13·4 ± 0·57 (10)
γ globulin	2·7 ± 0·23 (11)	2·1 ± 0·16† (10)

* $P < 0.02$.
† $P < 0.05$.
Number of animals shown in parentheses.

The results are shown in Table 1. The gain in weight was not significantly different between the two groups. Nor was the total serum protein changed by the cold exposure. This observation agrees with previous reports[3]. The constituent serum proteins did, however, display a significant change by a rise in serum albumin and a drop in the serum gamma globulin fraction in the cold-exposed group. Such a rise in the albumin fraction of the prairie meadow mouse is not consistent with the findings reported for the laboratory rat. Apparently this species of mouse is able to meet its energy needs without resorting to catabolism of albumin. Its energy needs are apparently supplied adequately from non-protein sources. The significantly elevated albumin levels further imply an increased osmotic effect associated with serum proteins. A fall in serum γ-globulin is suggestive of an increased rate of antibody turnover and a decreased rate of antibody production by animals exposed to cold. Trapani[4] found similar results with rabbits exposed to cold. A comparison of control serum protein fractions of the meadow mouse shows that they are of the same order of magnitude as the data reported by Moore[2] for the rat, but they disagree with Shields's rat data. As total protein was not measured by the latter authors, the low control albumin values reported (31 per cent) raise a question regarding the general health of their rats.

Additional similar investigations should be performed on other wild species to ascertain their response to cold stress. It is possible that the laboratory rat is unique in using albumin as an energy source when exposed to cold.

Decreased Lysosome Fragility in Response to Wounding in the Skin and Oral Mucosa of the Mouse

DURING a comparative histochemical investigation of repair in the skin and oral mucosa of the mouse, a marked change in the distribution of acid phosphatase activity in response to wounding was noted in the epithelial cells.

The Gomori lead nitrate technique, with all solutions made isotonic, was used to demonstrate enzyme activity in unfixed cold microtome sections. In the epithelium of normal skin and oral mucosa after incubation for 1·5 h, sites of enzyme activity were marked by particulate deposits of lead sulphide and by a diffuse cytoplasmic staining in the cells of the basal layers. Within 5 min of wounding (a single incision) the diffuse cytoplasmic staining was lost not only from the epithelial cells bordering the wound, but also from those some distance away from the wound margin (Fig. 1). The particulate deposits of lead sulphide persisted. Re-epithelialization occurred after 4 days, but the diffuse cytoplasmic staining did not re-appear until 7 days after wounding.

It is now generally agreed that sites of acid phosphatase activity in cells are confined to lysosomes or lysosome-like structures. Bitensky[1] has shown that the lysosome membrane has a given degree of fragility in the Gomori incubating medium, and that this varies not only for different tissues but also for the same tissue under differing experimental conditions. The diffuse and particulate deposition of lead sulphide obtained in this investigation indicates over-incubation and this was confirmed when a section of normal tissue was incubated for 1 h. In this case only a particulate deposition of lead sulphide marked sites of enzyme activity. However, as all the experimental

Fig. 1. Section through the skin surface of mouse lower lip 15 min after wounding. The wound margin is at the top left-hand corner of the photomicrograph. The epithelium adjoining the wound shows no diffuse deposition of lead sulphide. Gomori lead nitrate method. Incubation period 1·5 h

material was incubated for 1·5 h, the observed loss of diffuse cytoplasmic staining must represent a cellular response to wounding.

It was concluded that in both skin and mucosa there was a decreased lysosome fragility in the epithelial cells on both sides of the wound. This conclusion was tested by incubating an experimental section for 3 h and, as expected, there was a combined particulate and diffuse deposition of lead sulphide in the epithelium bordering the wound.

The functional significance of this decreased epithelial lysosome fragility in response to wounding is by no means clear, especially as Bitensky has demonstrated an increased fragility of lysosomes in damaged cells of other tissues. One can only speculate that the demonstrated decreased lysosome fragility indicates the cessation of some epithelial activity involving lysosomal enzymes, possibly keratinization, during the repair period.

Resistance to Shearing of Heat-denatured Muscle in Relation to Shortening

IF an excised beef muscle is exposed to a temperature of 0°–10° C soon after death, a shortening of considerable magnitude occurs during the subsequent 1–5 h[1]. Both the extent and the rate of shortening are less with higher temperature in this range, and also with longer delay before exposure to the cold environment. By appropriate selection of temperature and delay, therefore, shortening values ranging from nothing to more than 60 per cent of the initial length can be obtained.

During an attempt to account for this cold-shortening phenomenon we observed an effect of possible relevance to investigations of muscle structure. Strips of sternomandibularis muscle from beef animals, obtained within a few minutes of slaughter, were made to become shorter by a variety of methods: (*a*) exposure to air at 2° C, after storage at 15° C for 1–24 h; (*b*) storage from 1 h to 48 h *post mortem* at several temperatures within the range 0°–15° C; (*c*) immersion in ice-water for 0–24 h before freezing in solid carbon dioxide–alcohol; and (*d*) thawing muscles at different rates after freezing in solid carbon dioxide–alcohol in a pre-rigor condition. The unfrozen or thawed strips were sealed in plastic film, after the completion of normal rigor or thaw rigor changes, and heated in a water-bath to an internal temperature of 80° C. The force (F, arbitrary units) required to shear the heat-denatured fibres with a blunt metal wedge was then determined[2].

Only relatively low forces (F_{min}) were needed to shear those samples which had shortened (before heat treatment) by less than about 20 per cent of the initial length. Beyond this point, however, the force requirement rapidly increased with further shortening, in some cases doubling with an additional change in length equal to only 4–5 per cent of the initial length. Maximum force values (F_{max}), which always occurred in those strips which had become shortened by about 35–40 per cent, were two to four times the initial value, and there is evidence to suggest that this ratio (F_{max}/F_{min}) would have been even higher if the muscle selected for study had had a lower connective tissue content, and thus a lower shearing force requirement in the unshortened state.

In those muscle strips which had shortened by more than about 40 per cent, the force required to shear the samples was found to decrease with further shortening,

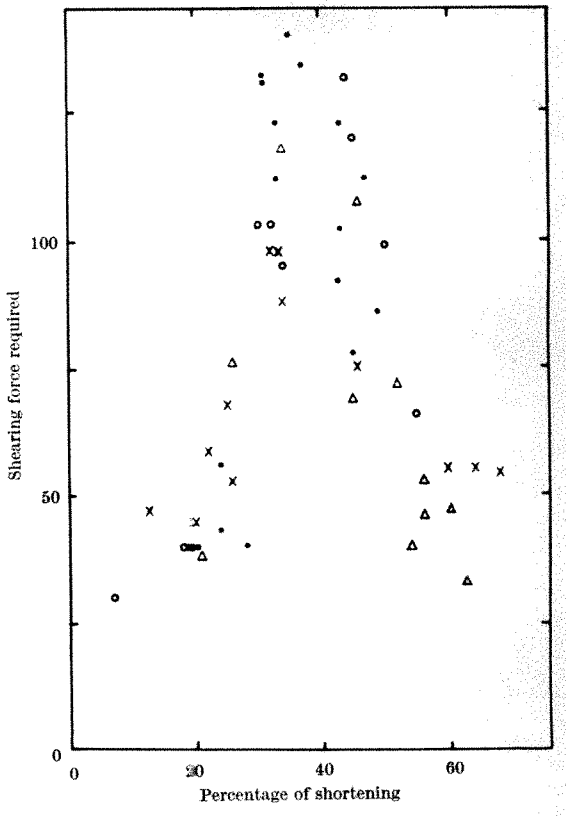

Fig. 1. The effect of degree of shortening on the force required to shear across the fibres of the heat-denatured muscle. Shortening produced by method (*a*) ○; (*b*) △; (*c*) ●; (*d*) ×

and at a considerable rate. The plot of force against shortening in the 40–60 per cent range, in fact, approximates to a mirror image of that in the 20–40 per cent range. The few results obtained from strips which had shortened by 60–65 per cent suggest that the force requirement remains low in this considerably shortened state, and about equal to that in the relatively unshortened condition.

The relationship between shortening and shearing force is illustrated in Fig. 1, which includes the results of one experiment for each of the four methods (*a*–*d*) already described to produce a range of shortening values. Our full results have revealed no exception in forty-two experiments which provided 530 points.

In this investigation, all shortening values were based on the initial length, that is, on the length of the muscle lying unrestrained for up to 1 h after excision, rather than on the true resting length of the muscle within the animal. If shortening had occurred as a result of excision and trimming[1], and before measurement of the initial length, then our critical shortening values of 20, 40 and 60 per cent would be too low. Despite this uncertainty which results from the absence of an absolute initial length, it is obvious from the magnitude of the changes in shearing force requirement that major structural changes have been detected at three distinct degrees of shortening.

The feature of this work most relevant to muscular contraction is the attainment of a peak force requirement at a certain shortening, followed by a reversal to low values with still further shortening. The effect would seem to be consistent with the sliding-filament theory of contraction[3]; the inter-digitating filaments present a resistance to perpendicular cleavage which is continuous along the structure (and therefore strong) at one degree of shortening, but regularly discontinuous (and thus more readily cleaved) on either side of it. It may also be significant

that the rapid decline in force requirement occurs at a shortening associated with the transition to the delta state[4], and when there is also a copious release of fluid indicative of membrane rupture[5].

Response of Alpha Motoneurones to Direct Electrical Stimulation during Desynchronized Sleep

THE homonymous monosynaptic reflex, as well as the polysynaptic reflex, elicited by single-shock stimulation of the primary afferents of a muscular nerve is tonically depressed during desynchronized sleep in the cat[1]. The depression of these reflexes, however, is not complete. A phasic enhancement of inhibition frequently occurs in relation to the rapid eye movements during deep sleep[1]. An analysis was made of the mechanisms responsible for the tonic and phasic inhibitory influences impinging on the spinal cord during desynchronized sleep by taking electromyographical recordings of the recurrent discharge of the α-motoneurones in deafferented limbs of unanaesthetized, free-moving cats[2]. It was found that this response is depressed throughout desynchronized sleep, but that no further reduction of the recurrent discharge occurs during the bursts of rapid eye movements[3]. A more direct way of evaluating the excitability of the α-motoneurones is to record their response to direct electrical stimulation. The best method would be, of course, to inject the testing current through an intracellular microelectrode. Because this technique cannot be adopted in experiments on free-moving, unanaesthetized cats, an attempt was made in stimulate extracellularly the pools of motoneurones to the ventral horn.

The volley produced by direct electrical stimulation of the motoneuronal pool was recorded from the tibial (extensor) or the deep peroneal (flexor) nerve in the deafferented hindleg. Single shocks were applied unipolarly to the ventral horns through a stainless steel microelectrode (100,000–600,000 Ω). This electrode[4], as well as the electrodes for the electroencephalographic recordings, the electromyographic recordings of the posterior cervical muscles, and for recording the ocular movements, were implanted chronically under 'Nembutal' anaesthesia. The experiments started 1–2 days after the operation, that is, when the effects of the anaesthesia had disappeared. Rectangular negative pulses (0·05 msec at 1·5–2/sec) were used at a strength of 1·2–1·8 times the threshold for the peripheral response. Because the dorsal roots had been cut, the volley produced in the muscular nerve could only have arisen from impulses propagating orthodromically along efferent fibres. Measurements of conduction velocity indicated that the discharge recorded travelled along α-efferent fibres. The size of the nerve action potential was taken as a measure of the number of α-motoneurones excited by the stimulus.

The orthodromic response of the motor fibres to direct stimulation of the motoneuronal pool elicited in either the tibial or the deep peroneal nerve was not modified during transition from relaxed wakefulness to synchronized sleep. Furthermore, during synchronized sleep no significant difference was observed between spindle periods

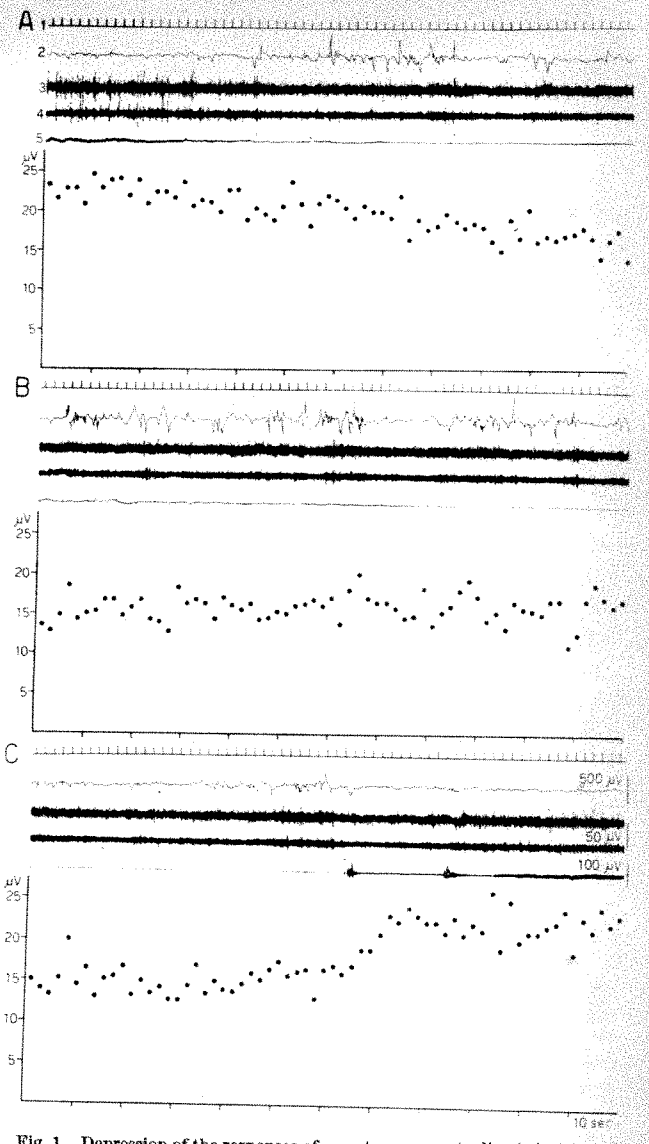

Fig. 1. Depression of the responses of α-motoneurones to direct electrical stimulation of the motoneuronal nucleus during sleep. Unrestrained, unanaesthetized cat. The experiment was carried out 2 days after chronic implantation of the electrode and complete deafferentiation of the left hindleg. A stainless steel microelectrode having a resistance of 100,000 Ω was chronically inserted into the motoneuronal nucleus supplying the deep peroneal nerve, while the orthodromic volley arising from direct stimulation of the α-motoneurones was recorded from the peroneal nerve with a bipolar electrode. (1) Stimulus artefact by stimulating the left ventral horn at the upper level of S_1 with rectangular pulses at one every 1·9 sec, 0·05 msec duration and 1·55 times the threshold for the orthodromic α-volley; (2) eye movements; (3) left parieto-occipital; (4) right parieto-occipital; (5) posterior cervical muscles. The amplitude of the volley arising from direct stimulation of the motoneuronal pool is represented by the position of the dots. *A*, Gradual depression of the responses of α-motoneurones during transition from synchronized to desynchronized sleep; *B*, soon after *A*, showing an episode of desynchronized sleep; *C*, recovery of the responses at the end of the episode of desynchronized sleep as monitored by the reappearance of the neck muscular activity

and interspindle lulls. The response of the α-motoneurones to direct stimulation was, however, tonically depressed during desynchronized sleep (Fig. 1). The decrease of the action potential was of the order of 20–30 per cent and lasted throughout the episode of desynchronized sleep. No phasic depression of motoneuronal excitability could be detected during the large bursts of rapid eye movements (Fig. 1).

These observations are in general agreement with those made on the recurrent discharge of α-motoneurones[3]. Both these methods of sampling the state of excitability of the α-motoneurones during physiological sleep and wakefulness lead to the conclusion that an increase in the

polarization of the motoneuronal membrane occurs during desynchronized sleep. This phenomenon, which is likely to arise from inhibitory postsynaptic potentials, would account for the tonic depression of the monosynaptic and polysynaptic reflexes which occur during desynchronized sleep[1].

Another mechanism must be postulated, therefore, to account for the striking phasic depression of the same reflexes that one sees in conjunction with the bursts of rapid eye movements[1]. The following evidence indicates that presynaptic inhibition, acting on the central endings of primary afferents, may cause the phasic depression of the spinal reflexes at the time of the rapid eye movements. No further depression of the motoneurones to antidromic[3] or direct stimulation (this report) was observed to parallel the bursts of rapid eye movements. In addition, during the bursts of ocular movements there is a phasic enhancement of the group I *a* antidromic volley[4], as tested in both flexor and extensor nerves following Wall's method[5].

Central Effects of β-*N*-Oxalyl-α,β-diaminopropionic Acid and other *Lathyrus* Factors

ALTHOUGH an association between β-aminopropionitrile derivatives and osteolathyrism of experimental animals seems well established[1], there is less certainty concerning the nature of toxic substances present in *Lathyrus* species responsible for human neurolathyrism[2]. Acute neurological manifestations are produced in some laboratory animals by L-α,γ-diaminobutyric acid (present in numerous *Lathyrus* species, but not in *L. sativus*)[3,4], by β-cyano-L-alanine (present in *Vicia sativa* and *V. angustifolia*, possible contaminants of *L. sativus*)[5] and by β-*N*-oxalyl-L-α,β-diaminopropionic acid (recently isolated from *L. sativus*)[6]. The degree of susceptibility to these toxic agents varies between different animal species, and it has yet to be demonstrated whether these substances do, in fact, produce human lathyrism. Nevertheless, in view of the potent effects of many relatively simple amino-acids on mammalian central neurones[7], these lathyrus factors are of considerable interest. Consequently an investigation has been made of the action of these and related compounds on single nerve cells of cats anaesthetized with pentobarbitone.

Action potentials were recorded extracellularly from spinal interneurones and Betz cells by means of the centre barrel of five-barrel glass micropipettes of overall tip diameter 4–5μ, while the compounds under investigation were administered electrophoretically into the immediate extracellular environment of single neurones from the other barrels[7]. Previously this technique has been used to demonstrate that certain acidic amino-acids related to glutamic acid are excitants of nerve cells, whereas structurally similar neutral amino-acids of the γ-aminobutyric acid group are depressants[7].

β-Cyano-L-alanine, β-cyano-D-alanine, α-cyanoglycine and γ-cyano-L-α-aminobutyric acid neither excited nor depressed spinal interneurones when administered as cations from aqueous solutions of *p*H 2·8–3·4. When similarly administered, L-α,γ-diaminobutyric acid depressed the synaptic responses of these cells, but had a much weaker action than γ-aminobutyric acid or β-alanine[7]. In marked contrast, however, β-*N*-oxalyl-L-α,β-diaminopropionic acid, administered as an anion from a *p*H 7·5 solution of the sodium salt, was a powerful excitant of spinal interneurones and Betz cells. This substance was more potent than D,L-homocysteic acid, and was only slightly less active than *N*-methyl-D-aspartic acid, the strongest amino-acid excitant of feline nerve cells yet reported[7]. When injected intraventricularly into 4-week-old mice[8], β-*N*-oxalyl-L-α,β-diaminopropionic acid caused flexor convulsions and hyperactivity in doses of 25–50 μg. Related amino-acids, γ-*N*-oxalyl-α,γ-diaminobutyric acid, *N*-oxalylglycine and *N*-oxalyl-β-alanine were without effect on spinal interneurones.

β-*N*-Oxalyl-L-α,β-diaminopropionic acid is thus the most powerful excitant L-amino-acid yet tested. It is tempting to speculate that a direct action on central neurones accounts for the effects which follow intraperitoneal administration to immature chickens[6], and that the lack of action on mice and rats[6] is associated with the failure of the amino-acid to penetrate the blood-brain barrier. If this barrier is relatively impermeable in adult animals, then difficulties may arise in explaining the relationship between the oxalyl derivative and human lathyrism, unless of course the diffusional barrier is altered by severe nutritional deficiencies. Presumably the toxic effects produced by β-cyano-L-alanine[5] and L-α,γ-diaminobutyric acid[3] are not produced by a direct action on nerve cells, and may be associated with disturbances of the metabolism of L-glutamic acid, γ-aminobutyric acid and related substances.

We thank Dr. C. Ressler for samples of cyano-amino acids, Prof. P. S. Sarma for a sample of natural β-*N*-oxalyl-L-α,β-diaminopropionic acid and some synthetic oxalyl derivatives of amino-acids, and Dr. D. R. Rao for bringing the recent work of Prof. Sarma and his colleagues to our attention.

Fate of Intracisternally Injected 5-Hydroxytryptamine in the Rat Brain

THE uptake of 5-hydroxytryptamine (5-HT) by brain tissue *in vitro* and *in vivo* has been investigated by many workers[1–4]. The present experiments investigate the fate of 5-HT in the brain tissue after administration into cerebrospinal fluid.

Albino male rats weighing 110–130 g were used. The animals were anaesthetized with ether and received an intracisternal (cisterna magna) injection[5] of 5-HT solution. 5-Hydroxytryptamine creatinine sulphate (Light) was dissolved in an isotonic solution of sodium chloride and administered in a dose of 0·1 mg/100 g body-weight.

To obtain bloodless brain, the animals were bled with simultaneous intravenous infusion of saline until the effluent was almost colourless. After decapitation, the cerebral ventricles were opened, the arachnoid was cut with a razor blade and the whole brain was washed with running saline to remove cerebrospinal fluid. In this way, all 5-OH indoles outside the brain tissue are probably removed. The animals were killed in this way at various intervals after injection. The whole brains were homogenized with 0·1 N hydrochloric acid. After precipitating the proteins with 10 per cent zinc sulphate and 10 per cent sodium hydroxide, portions were taken for spectrofluorimetric determination of total 5-OH indoles[6], 5-hydroxyindoleacetic acid (5-HIAA)[6] and 5-HT[7].

The results are shown in Fig. 1. It is clear that 5-HT penetrates into the brain very easily. The maximal level is achieved 10 min after injection. There is a rapid decline in 5-HT content from 20 to 40 min. A progressive but less rapid fall in 5-HT is manifested from 40 to 80 min.

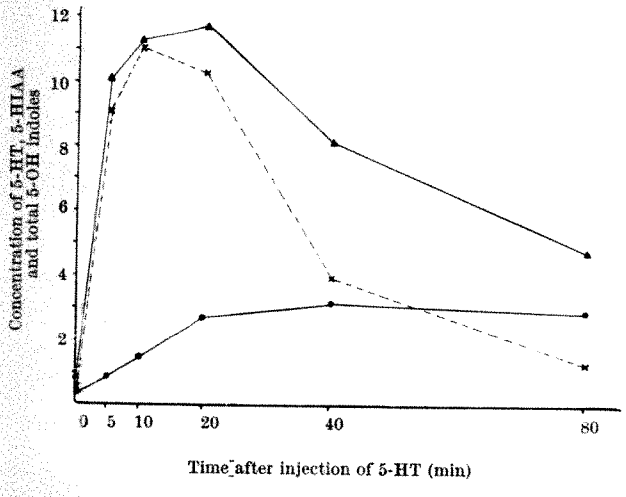

Fig. 1. Amount of 5-HT, 5-HIAA and total 5-OH indoles in the rat brain (μg/g) at various intervals after intracisternal (cisterna magna) injection of 5-HT (0·1 mg/100 g body-weight). Each point represents mean of five experiments. × — — — ×, 5-HT; ●——●, 5-HIAA; ▲——▲, total 5-OH indoles

The content of 5-HIAA, main metabolite of 5-HT, increases continuously up to 40 min. Thereafter it remains almost unchanged.

The amount of total 5-OH indoles oscillates, depending on the levels of 5-HT and 5-HIAA.

Surprisingly, the rapid decrease of 5-HT from 20 to 40 min is not followed by an adequate increase of 5-HIAA. This discrepancy could be explained in many ways: 5-HIAA rapidly leaves the brain; 5-HT is not completely metabolized via 5-HIAA; 5-HT leaves the brain partly unchanged.

Comparing the results from our previous work[8] with those described, it is evident that 5-HT penetrates from cerebrospinal fluid into the brain in a far greater amount than from blood. There are many possible reasons for this phenomenon. (1) 5-HT may be rapidly taken up by blood platelets. (2) 5-HT may be carried by blood in the different tissues and metabolized. (3) 5-HT may be very diluted when given intravenously, the volume of the blood being greater than that of the cerebrospinal fluid.

Summarizing the results of our experiment, it can be concluded that intracisternally administered 5-HT penetrates into the brain easily. Its metabolism is very rapid in the brain and it is almost complete after 80 min.

PHARMACOLOGY

Effect of Methylhydrazine Derivatives on the Survival of Second-set Skin Homografts

METHYLHYDRAZINE derivatives were originally introduced as a new class of anti-tumour agents[1]. Since then, as with other cytotoxic drugs, immunosuppressive effects have also been demonstrated[2,3]. In an investigation of the pharmacological susceptibility of the primary skin homograft reaction, it became increasingly clear that the methylhydrazine derivatives were among the few agents which provided a definite prolongation of graft survival in mice[4]. The present experiments were carried out to determine the effect of these compounds on the survival of second-set skin homografts.

Inbred strains of mice were used. Skin grafting was done by the method of Billingham and Medawar[5]. Grafts were taken from the general body skin of donors. The dressings were removed on the sixth day and the grafts were inspected daily thereafter. The survival times were taken as end points, that is, until complete graft breakdown was evident. 'White grafts', when present, were lost shortly after the removal of the dressing and were then classified as surviving 6 days.

First-set homografts had been applied to the contralateral side of the backs of the mice 3–5 weeks before the second transplant. The donor and recipient animals were both of the same sex.

Two methylhydrazine derivatives were used for treatment: *Ro* 4–6467/1 (= 1-methyl-2-*p*-(isopropylcarbamoyl) benzylhydrazine hydrochloride) and *Ro* 4–6824 (= 1-methyl-2-*p*-allophanoylbenzyl = hydrazine hydrobromide). In addition, *cyclo*phosphamide and azathioprine were included in the strain combination *C57BR←CBA*. The drugs were applied daily subcutaneously, beginning on the day of transplantation or 12 days beforehand. Two doses were used for each compound. According to preliminary trials, they were of approximately equal toxicity during administration over a period of several weeks.

Table 1 shows the prolongation of the survival of second-set skin homograft, provided by *Ro* 4–6467/1 and *Ro* 4–6824 in mice. Definite prolongations in comparison with the untreated control groups were obtained in two donor/recipient combinations. In the first, transplants from F_1 hybrids between two strains with 'strong' histocompatibility differences were placed on a parent strain (*C57BL←(CBA* × *C57BL)*F_1). Fig. 1 represents the respective individual graft survival times. The second combination (*C57BR←CBA*), as characterized by its first-set skin homograft survival time of 9·6 days[4] behaved like one with 'strong' antigenic differences and *H*-2 locus disparity. In these two combinations, with an effective drug regimen, the prolongation of the survival of the second-set graft was of the order of 50–70 per cent.

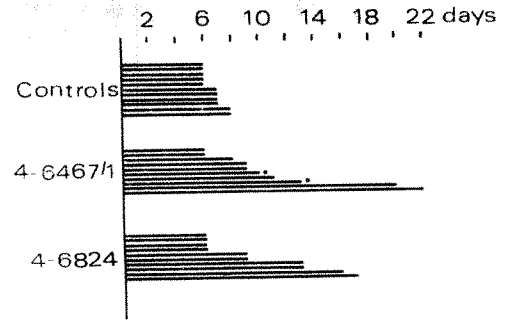

Fig. 1. Prolongation of $(CBA \times C57BL)F_1$ second-set skin homograft survival in *C57BL* mice given *Ro* 4–6467/1 and *Ro* 4–6824 daily (150 mg/kg, from day −12). See also Table 1. ○, Mice died before the rejection of the graft was completed

In contrast, *cyclo*phosphamide and azathioprine did not significantly retard the rejection of *CBA* grafts on *C57BR* hosts. Small but statistically significant extension of graft survival was caused by the methylhydrazines in the combinations *C3H←C-* and *CBA←A*. As twenty-four of twenty-five control grafts were already rejected at the first evaluation, inspection on day 5 rather than on day 6 might have led to somewhat more pronounced results.

When the two methylhydrazine derivatives are compared, it is clear that although they have practically equal immunosuppressive activity, *Ro* 4–6824 is less toxic in mice. Treatment of the hosts before grafting was more effective than treatment from the day of transplantation onwards. These two observations confirm earlier findings made with first-set skin homografts[3,4].

The second-set homograft reaction is considered highly resistant towards modification by radiation or drugs. To our knowledge, no drugs have been successful when applied to this purpose. In temporarily successful organ transplantation, as with kidneys, a constant antigenic stimulation is likely to occur. Therefore, immune states might develop which resemble the situation in second-set transplants. Drugs which affect the second-set model might consequently, besides facilitating the acceptance of primary transplants, also be indicated to control such phenomena in clinical organ transplantation as the late 'acute rejection crises', which are considered as attempts of the host to destroy primarily accepted organ homografts.

The biological mechanism by which the methylhydrazine derivatives exert their action is not yet fully understood. The marked and clinically predominant effect of *Ro* 4–6467/1 in malignant lymphoma[6,7] seems to indicate a specific vulnerability of lymphoid tissue. The intensively proliferating lymphoid cells which characterize the secondary immune response to homografts are likely to be an equally sensitive target for these drugs.

We have also found a relatively pronounced effect of the methylhydrazine derivatives on transplantation immunity in experiments now in progress using skin homografts in rabbits. The use of these agents in clinical organ transplantation, particularly with adequate pretreatment, should be more thoroughly assessed.

I thank Miss Maryan Richner for skilful technical assistance.

BIOCHEMISTRY

Direct Effect of Vitamin A on Boar Testis

ABOUT 40 years ago the effect of vitamin A deficiency on male sexual organs was investigated in rats by Wolbach and Howe[1] and Gross[2], and in guinea-pigs by Wolbach and Howe[3]. Later the influence of this vitamin on reproduction was investigated in various species of domestic animals, for example, in bulls by Hodgson *et al.*[4] and Madsen *et al.*[5,6], and in rams by Lindley *et al.*[7], but until I reported my investigations[8], it would seem that boars had not been examined. Termination—or a marked reduction—of the spermatogenesis as a consequence of the A-avitaminosis characterized all findings in the species of animal examined. It was demonstrated in these experiments that the administration of vitamin A to an A-avitaminotic boar resulted in complete normalization of the spermatogenesis within 3 months.

Investigations were continued with the view of elucidating whether vitamin A acted directly on the spermatogenetic epithelium or whether a hormonal factor was involved.

As with previous experiments, Danish Landrace boars were used, and from the age of 6 weeks were fed a diet deficient in vitamin A. The vitamin A status was controlled by analysis of liver biopsies which, together with the markedly increased cerebrospinal pressure, formed the basis by which it was checked that the animals (at the age of 4–5 months) were depleted of vitamin A. At this stage, daily doses of vitamin A acid were supplied to some of the boars, the clinical condition of which remained normal but in which a vitamin A deficiency was manifest in the spermatogenetic tissue. This feature was investigated earlier in boars (unpublished data), and is in accordance with findings of Thompson *et al.*[9] in rats. About a month later, vitamin A alcohol or vitamin A aldehyde in peanut oil containing small quantities of indian ink was injected into one of the testicles. The doses of vitamin A alcohol injected varied between 6,000 and 8,000 I.U., and vitamin A aldehyde between 0·6 and

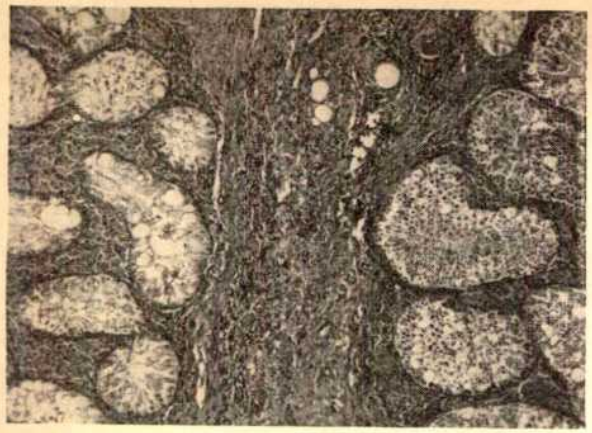

Fig. 1. Testis from vitamin A-deficient boar. The septula testis, which contains vacuoles and grains of indian ink, separates normal spermatogenetic tubules (right) from degenerating tubules (left). (Stained with haematoxylin-eosin. × 60)

1·6 mg. In a few boars, both preparations were applied to the same testicle, one preparation being injected at a distal, the other at a proximal site. At intervals of 3–4 weeks this treatment was repeated on four or five occasions after which the animals were killed.

The weight of the testicles was found to be much lower in all experimental boars than in their normal littermates; members of the former group were about a third or a half the normal weight. There was no characteristic difference in weight between treated and non-treated testicles. Histological examination of the testes, however, revealed a distinct difference between the testicular areas into which the vitamin had been injected and the surrounding tissue and the non-treated testicle. In some boars spermatogenesis was found to be normal at the site of application (Fig. 1), yet at the same time there was total degeneration of the spermatogenetic epithelium in the surrounding tissue and the non-treated testis as the tubules were found to contain only Sertoli's cells and a few inactive spermatogonia. Generally the areas treated with vitamin A were well defined, and radial septa of testicular connective tissue separated the vitamin A-rich from the vitamin A-deficient areas (Fig. 1). Besides the normal spermatogenesis in the former areas, grains of indian ink could be seen embedded in the interstitial tissue which also contained some circular or oval vacuoles of somewhat variable sizes. These vacuoles represented the 'negative picture' of the vitamin A-containing peanut oil used for the injection, and fat-staining of frozen sections of the testicles with Sudan III gave a positive result. Vitamin A alcohol and vitamin A aldehyde thus seem to have similar direct effect on the spermatogenetic tissue, with the exception that vitamin A aldehyde seems to result in a more well-defined demarcation between the active, vitamin-treated and the vitamin-deficient testicular tissues.

As already mentioned, the way in which the vitamin A deficiency provokes the characteristic testicular changes remains unknown. An explanation which immediately suggests itself is that it might be a matter of hormonal interference, and for this reason interest has been focused primarily on the gonadotropic hormones of the pituitary. The results obtained in investigations using experimental as well as domestic animals have been most contradictory. Whereas Mason and Wolfe[10] found that the content of gonadotropins in the pituitary increases in vitamin A-deficient rats, Van Os[11] and Mayer and Goddard[12] considered that supplies of gonadotropic hormones would counteract the degenerative influence on the sexual organs otherwise involved in such vitamin deficiency. Hodgson *et al.*[4] and Gunn *et al.*[13] (the former group used A-avitaminotic bulls, while the latter group used rams) found that the spermatogenesis was accelerated after administration of pregnant mare serum; however, Lindley *et al.*[7] in more comprehensive experiments with rams showed that supplies of pregnant mare serum failed to prevent the development of A-avitaminotic, testicular changes.

As early as in 1952 Fell and Mellanby[14] demonstrated in tissue cultures that high dosages of vitamin A might be responsible for a cellular A-hypervitaminosis and that consequently they might be considered to act directly on cells *in vitro*. Numerous experiments carried out by Fell[15] substantiated this finding, not merely in A-hypervitaminosis but also in A-hypovitaminosis.

Thus our findings show that the degenerative changes of the spermatogenetic tissue caused by A-avitaminosis are not indirectly provoked by changes—arising from the avitaminosis—in the hormonal regulation, but instead that they are of a direct nature. That is to say, they can be attributed to a disturbed function of the spermatogenetic tissue brought about by the vitamin A deficiency, and thus can be counteracted by direct application of vitamin A alcohol or vitamin A aldehyde to the tissue, but not by application of vitamin A acid.

Separation of Connective Tissue Mucopolysaccharide–Protein Complexes from Unrelated Proteins

IT is now generally accepted that most, if not all, of the mucopolysaccharides (MPS) in connective tissues are bound to small amounts of protein or peptide. Recent estimates indicate that this protein content may be as little as 2 per cent for hyaluronic acid and as much as 15–20 per cent for cartilage protein–polysaccharide complexes[1]. Crude extracts of connective tissue always contain large amounts of protein not associated with the MPS. Therefore, in almost all procedures for isolating the MPS components, deproteinization is an essential first step before purification. It is usually assumed that the variety of proteolytic enzymes used, such as pronase, papain or trypsin, specifically degrade the "unrelated" protein but do not attack that complexed to the MPS. Although this is probably true there is, nevertheless, little direct experimental evidence to support this assumption. Other methods commonly used to deproteinize crude tissue extracts are adsorption on kaolin, Lloyd's reagent, shaking with chloroform-isoamyl alcohol (Sevag's procedure) and dialysis against a cationic resin[2]. Besides the possibility of degradation, these procedures generally result in great losses of material.

It seemed desirable to find milder methods for the deproteinization of crude extracts, especially those

derived from tissues with only small amounts of MPS. The present communication describes a procedure in which the ratio of protein and uronic acid can be reduced from 70/1 to as little as 5/1 by passing crude tissue extracts through columns of *CM*- or *SE*-'Sephadex'. Besides the rapidity and simplicity of this procedure, it has the additional advantage of causing little loss of MPS. These strongly acidic substances, being repelled by the fixed negative charges of the gel, pass quantitatively through the column while most of the proteins are retained on the gel. At this stage, when only relatively little protein remains, most of it can be removed by the addition of 55 per cent ammonium sulphate.

The *CM*- and *SE*-'Sephadex', *A*-50 Medium (Pharmacia) were washed first with 0·5 N hydrochloric acid and afterwards with buffer; the latter step is a very critical one since it was found that maximum adsorption of protein could be achieved only under carefully controlled conditions. Whereas relatively little protein is retained on the column when phosphate buffer, *p*H 6·5–7·0, is used, maximum adsorption can be attained with citrate-phosphate buffer at *p*H 5·2–5·5. The ionic strength of the starting buffer is not critical; buffers ranging from 0·005 M to 0·02 M were found to be equally effective. Although the *CM*-'Sephadex' requires a considerable number of washings before equilibrium is reached[3], *SE*-'Sephadex' was found to equilibrate very rapidly. Both are equally effective in adsorbing proteins. Columns 2–3 cm in diameter and 30–50 cm in height were used in all the experiments. Tissue extracts were dialysed against two changes of starting buffer. Any residue which formed was removed by centrifugation and the dialysed supernatant solutions were then applied directly to the column.

The results of two typical experiments are summarized in Table 1. The initial ratio of protein/uronic acid in an extract of bovine cornea was 42/1; after two passages through *CM*-'Sephadex' this ratio had dropped to 6·2/1. A similar fall in the ratio of protein/uronic acid was observed in preparations obtained from cattle retina[4]. The largest amount of protein which can be applied to a column of this size is about 250 mg. Samples containing quantities greater than this are best chromatographed in batches.

Table 1. PURIFICATION OF CONNECTIVE TISSUE EXTRACTS

Tissue	Protein* (mg)	Uronic acid† (mg)	Protein/uronic acid

* Assayed according to the method of Lowry *et al.* (ref. 5).

† Assayed according to a modification (ref. 6) of the carbazole method of Dische (ref. 7).

It should be noted that passage through *CM*- or *SE*-'Sephadex' did not completely remove all the protein initially present. Moreover, additional chromatography did not cause any further drop in the ratio of protein/uronic acid. However, it was afterwards found that at this stage the relatively small amount of protein remaining could be removed almost completely by precipitation with 55 per cent ammonium sulphate; almost no loss of uronic acid-containing material resulted. Ammonium sulphate is apparently only effective at relatively low protein concentrations. When added to the crude extracts, considerable loss of MPS resulted, due undoubtedly to co-precipitation of mucopolysaccharide–protein complexes with the protein.

To sum up, the overall procedure outlined here results in the removal of about 98 per cent of the original protein in these preparations, while substances containing uronic acid are recovered in yields of 80 per cent or more. It may be assumed that a substantial portion of the protein remaining is probably bound to the MPS. The mild conditions used undoubtedly ensure the preservation of these complexes in their native state, and thus provide suitable starting material for ultimate fractionation and purification. Because of the high recovery of uronic acid-containing substances, this procedure is especially suitable for tissues with low MPS content.

I thank Prof. I. C. Michaelson for his interest in this work, Mrs. R. Gast for technical assistance and Mrs. S. Saliternik-Givan for analyses of the corneal extracts. This work was supported in part by grants from the U.S. Public Health Service, National Institutes of Health and the National Council to Combat Blindness, Inc.

Anomalous Protein Binding of Iodine-131 in the Presence of Iodate

As a preliminary step to some work which we wish to undertake with insulin labelled with iodine-131 and other proteins, we have recently compared some of the methods available for the separation of protein-bound iodine and free iodine from mixtures of the two.

In the course of this work we have studied the behaviour of two mixtures, containing human serum and iodine-131 in the form of sodium iodide and with the addition of either inactive sodium iodide or iodate. In the presence of sodium iodide alone, it has proved possible to effect virtually complete separation of the iodide from the serum (as determined by distribution of radioactivity) by (i) trichloroacetic acid precipitation, (ii) zinc hydroxide precipitation, (iii) separation on ion exchange resin, and (iv) gel filtration. In the presence of iodate, however—though the latter three methods gave results comparable with those found with iodide—precipitation with trichloroacetic acid gave completely anomalous results and 74 per cent of the activity was found in the precipitate. This is demonstrated quite clearly by the summary of results given in Table 1.

The mechanism for this precipitation of the activity is not clear. The fact that the molecular sieving achieved by the gel filtration indicates the activity to be associated

Table 1

Method of separation	Percentage of total radioactivity associated with protein in the presence of Sodium iodide	Sodium iodate
(i) Trichloroacetic acid	1·0	74·0
(ii) Zinc hydroxide	2·0	3·0
(iii) Gel filtration	1·0	2·0
(iv) Ion exchange	1·0	4·0

Notes: (*a*) The mixtures consisted of 10 ml. of pooled human serum to which had been added approximately 2 μc. of iodine-131 and 5 mg of either sodium iodide or iodate. 0·5 ml. portions of these were used for all determinations. (*b*) Trichloroacetic acid precipitations were carried out with 5 per cent trichloroacetic acid. The precipitates were centrifuged and washed three times with 5 ml trichloroacetic acid. (*c*) The procedure adopted for the zinc hydroxide precipitations was that developed by Somogyi (ref. 3). (*d*) Gel filtration was performed on 20 cm × 1 cm columns of 'Sephadex *G*-25', using normal saline as the eluent. (*e*) Columns containing about 1·5 g of 'Amberlite' resin *IRA* 400 Cl were used for the ion exchange separations and normal saline was again used as the eluent.

with small molecules would seem to preclude true protein binding of the iodide. Moreover, the objections which have been raised in the past with regard to the use of trichloroacetic acid as a precipitating agent for protein-bound iodines[1,2] (on the grounds that inorganic iodine is occluded in the precipitate) would appear to be only partially valid; in *in vitro* conditions at least, the phenomenon only occurs in the presence of iodate.

Though doubts have been cast on the accuracy of the method, the precipitation of protein-bound iodine by trichloroacetic acid in thyroid function tests is well established. The technique has also been used as a criterion of the degree of protein labelling achieved in methods in which iodinating mixtures containing iodide and iodate are used. Our findings suggest that results obtained by this method should be examined critically, as very different results can be obtained when other methods of separation are used.

Actomyosin-like Protein from Crayfish Nerve: a Possible Molecular Explanation of Permeability Changes during Excitation

THE purpose of this communication is to show that a protein which resembles the contractile actomyosin of muscle (also an ATPase) is present in nerve membranes.

A detailed hypothesis has been presented elsewhere[1], together with supporting evidence, suggesting that the complex permeability of the membrane of excitable cells is controlled by an adenosine triphosphatase (ATPase) enzyme system, which is able to change its molecular configuration as a function of the supply of energy-rich substrate. Changes in effective pore diameter and/or position of charged groups would produce a modification of selective cation-permeability. Such a "mechanoenzyme" system[2] would correspond with that present in the mitochondrial membrane[2,3] and would account for the changes in axon length[4] and in light scattering properties of the axon membrane[5] which follow electrical stimulation. Its enzymatic activity would also contribute to the observed changes in inorganic phosphate liberation which follow nerve activity[6].

Crayfish (*Astacus pallipes*) nerve cords were homogenized and suspended in a solution of 0·25 M sucrose and 1 mM ethylenediamine tetraacetic acid (EDTA), buffered with 30 mM *tris* at *p*H 7·3. The homogenate was centrifuged at 0° C and the nuclear and mitochondrial fractions discarded. The resulting supernatant was diluted with an appropriate solution of salts (AnalaR grade) in *tris* buffer and examined in a Hilger–Watts recording spectrophotometer. Changes in absorbancy at 19° C were measured at a single wave-length 410 mμ[3]. Each cuvette contained approximately the supernatant from three nerve cords; this was equivalent to a final dilution of 0·8–1·2 mg protein/ml. Determinations of enzyme activity were made by incubation with ATP (*tris*-salt, Sigma) and the inorganic phosphorus (P_i) liberated was measured by the method of Fiske and Subbarow[7].

The supernatant was found to possess ATPase activity, with both glycoside-sensitive and glycoside-insensitive fractions, as found in the membrane fragments of crab nerves[8].

When the preparation was placed in the spectrophotometer its absorbance was in the range 0·17–0·25, when compared with a distilled water blank. However, the absorbance and turbidity of the preparation proved to be very sensitive to the effect of the addition of ATP. At *p*H 7·3 and with an ionic concentration of Na^+ = 80 mM, K^+ = 120 mM, Mg^{2+} = 4 mM, the addition of ATP to a final concentration of 2 mM produces an increase in absorbance (approximately 50 per cent), but higher concentrations of ATP (4–6 mM) cause large absorbancy changes. The action of ATP is clearly diphasic. On the addition of ATP there is a large initial increase in absorbance, followed by a slow, steady increase, the rate of which declines over the following 45 min. Small variations in the value of the absolute turbidity change were found, but typical results are illustrated in Table 1, experiments 1–4. Essentially the same overall pattern of changes in absorbance was obtained when either the ATP was added at one time or in successive smaller quantities, although successive application produced a higher overall change (Table 1). The large initial changes at 4 and 6 mM ATP were clearly evident by eye.

These changes in the absorbancy of the supernatant are very sensitive to ionic concentration and *p*H and to their interacting effects. For example, reducing the ionic concentration to Na^+ = 15 mM, K^+ = 15 mM, Mg^{2+} = 6 mM, *tris* 30 mM increased the magnitude of the absorbancy change produced when ATP was added. This effect was accentuated still further by the removal of all cations except Mg^{2+} (6 mM). When the *p*H of the medium was reduced to 5·5 or 6·5, in the presence of 6 mM Mg^{2+} only, low concentrations of ATP (0·5–1·0 mM) were sufficient to produce very large increases in turbidity. On the other hand, the preparation was very much more stable in the presence of ATP when the *p*H was raised to 7·4 and only small changes in absorbancy were recorded.

These results concerning the superprecipitation produced by ATP, and the effects of ionic concentration and *p*H, are characteristic of actomyosin-like proteins[9] and provide evidence for the presence of a similar contractile system in the nerve membrane. Two fractions of ATPase activity are known to be present in the excitable mem-

Table 1. ATP-INDUCED CHANGES IN TURBIDITY OF SUPERNATANT, AS MEASURED BY ABSORBANCY, *A*, AT 410 mμ

Expt. No.	Ouabain 10^{-4} g/ml.		Initial reading	ATP concentration 1·5 mM 10″	1·5 mM 30′	2·0 mM 10″	2·0 mM 30′	2·5 mM 10″	2·5 mM 30′	3·0 mM 10″	3·0 mM 30′	3·5 mM 10″	3·5 mM 30′	4·0 mM 10″	4·0 mM 30′	6·0 mM 10″	6·0 mM 30′

		per cent				11	48							184	471	514	735
	+	*A*	0·178			0·200	0·295							0·524	1·074	1·183	1·545
		per cent				12	66							194	503	564	768
(2)	–	*A*	0·254	0·271	0·271					0·420	0·593						
		per cent		7	7					65	133						
	+	*A*	0·255	0·286	0·286												
		per cent		12	12												
	–	*A*	0·254					0·316	0·387								
		per cent						24	52								
(3)	+	*A*	0·190													0·740	1·180
		per cent														289	521
(4)	–	*A*	0·226	0·242	0·244			0·289	0·607			0·714	1·038				
		per cent		7	8			28	169			216	359				
	+	*A*	0·288			0·254	0·410			0·510	0·960						
		per cent				11	79			123	317						

At each successive addition of ATP, the change in turbidity is also expressed as a percentage of the initial absorbancy.
Spectrophotometer readings show 'immediate' response at 10 sec (10″) and after 30 min (30′). *p*H = 7·3, 19° C. Ions, Mg^{2+} = 4 mM, K^+ = 120 mM, Na^+ = 80 mM, *tris* = 30 mM.

brane, one glycoside-sensitive and the other glycoside-insensitive. The former is associated with the active cation pump[8,10], and it is suggested[1] that the latter controls the passive permeability of the membrane. Addition of the glycoside ouabain does not significantly alter the superprecipitation effects produced by ATP (experiments 1 and 2, Table 1). However, the process of superprecipitation followed an approximately exponential time course over the 30 min period after addition of ATP, whereas parallel enzyme investigations showed that the rate of ATP hydrolysis at 19° C was low and followed a linear time-course. Furthermore, at the higher ATP concentrations the enzymatic activity of ATPases is inhibited[8,10], while in our experiments increased superprecipitation is observed at these substrate concentrations. The observation that the addition of ouabain has little effect on the process of superprecipitation does not, therefore, necessarily exclude the possibility that the cation pump is also associated with the activity of a contractile protein. The action of low *p*H in accelerating superprecipitation confirms the view that this phenomenon is not directly related to enzyme activity. Either one or, more probably, both of the ATPase components could be a protein able to change its molecular configuration on the addition of ATP. The results correspond with the actomyosin-like protein which has been identified[11] in and isolated[12] from the mitochondrial membrane, and the results of experiments concerning the permeability of erythrocytes[1,13] also strongly suggest that a comparable system that controls permeability is present in the erythrocyte membrane.

The concentrations of ions and ATP used in these experiments are either identical with[14] or correspond very closely with[8,10] those used in many of the classical studies concerning the ATPase enzyme activity of nerve and erythrocyte membrane. The superprecipitation produced at 4 and 6 mM ATP might explain the substrate inhibition observed in other experiments at concentrations of 2·0–2·5 mM and greater[8,10].

New Assay of the Ribonuclease-reactivating Enzyme based on Disulphide Exchange

RECENTLY, Straub and I described experiments which suggested that the ribonuclease-reactivating enzyme isolated from pig pancreas probably acts through a rearrangement of disulphide bridges of the substrate by means of disulphide–sulphydryl interchange[1,2]. Further evidence in favour of this hypothesis has been reported by Givol *et al.*[3]. However, the action of this enzyme was followed in both laboratories by indirect methods, that is, by measuring the rate of appearance or disappearance of the activity of another enzyme (ribonuclease or chymotrypsin). This communication describes a convenient assay method which eliminates many uncertainties of the indirect reactivation–inactivation tests and further supports the proposed interchange mechanism.

The substrate used in this assay was a randomly mixed disulphide, formed from radioactive cysteine and reduced ribonuclease. Reduced ribonuclease[4] (1 mg/ml.) and sulphur-35-labelled cysteine (20 μg/ml., 2×10^6 c.p.m./ml.) were allowed to oxidize spontaneously at *p*H 8·5 in 8 M urea for 120 h. When the reaction was complete, the mixture was filtered through 'Sephadex *G*-25' gel equilibrated and eluted with 0·1 N acetic acid. The macromolecular fraction which contained 9 per cent of the originally added radioactivity was lyophilized and dissolved in a small volume of 0·1 N acetic acid. When this

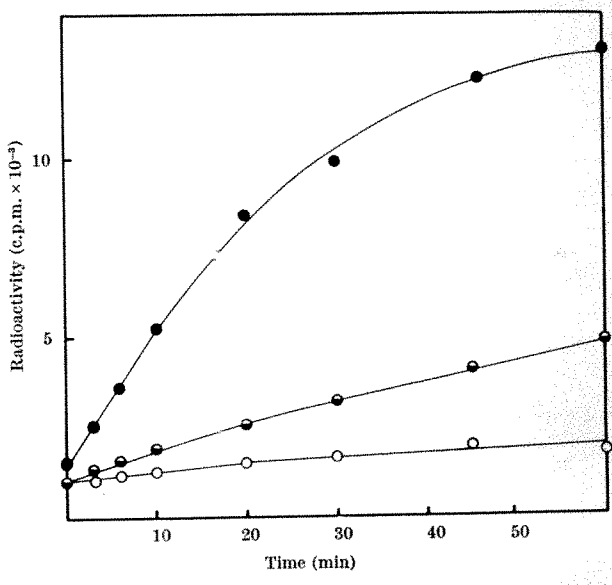

Fig. 1. Time curve of the release of soluble radioactivity. Incubation mixture: 0·2 M *p*H 7·5 *tris*-hydrochloric acid; 10^{-5} M labelled substrate (3×10^4 c.p.m.) in 1 ml. volume. ○, No addition; ◒, 5×10^{-5} M 2-mercaptoethanol added; ●, 5×10^{-5} M 2-mercaptoethanol added with 180 μg enzyme. The measured radioactivities were calculated to the total incubation mixture and plotted against time

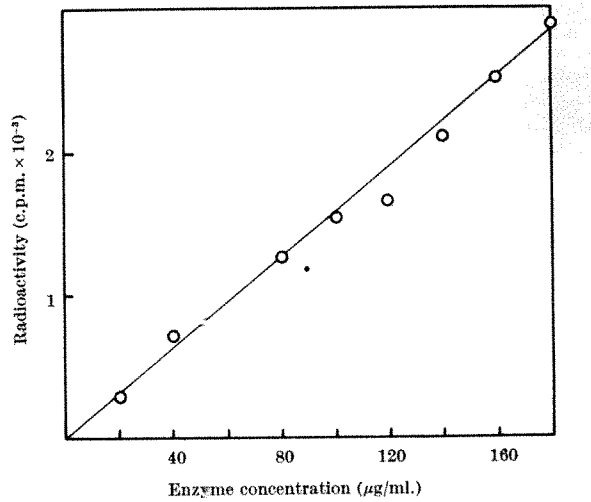

Fig. 2. Enzyme concentration curve. Incubation mixture: 0·2 M *p*H 7·5 *tris*-hydrochloric acid; 10^{-5} M labelled substrate (3×10^4 c.p.m.); 5×10^{-5} M 2-mercaptoethanol; plus varying amounts of the enzyme. Volume: 1 ml. Incubation time: 10 min. The control value (radioactivity released in the absence of enzyme) was subtracted from the measured radioactivities

substrate was incubated with the partially purified RNase-reactivating enzyme[5], radioactivity was released from the protein. The assay was carried out as follows. The labelled substrate was incubated at 30° C in *p*H 7·5 *tris* buffer in the presence of the enzyme and 2-mercaptoethanol. At various intervals, 0·1 ml. portions of this mixture were pipetted into 2 ml. cold acid–acetone (acetone : 1 N hydrochloric acid, 39 : 1). 0·05 ml. of 2 per cent serum albumin solution was added as carrier and the precipitated protein was removed by centrifugation. Equal portions of the supernatant solutions were dried on alumina planchets and their radioactivities determined by means of a windowless gas-flow counter.

Fig. 1 shows the increase of soluble radioactivity in the presence or absence of the enzyme. Fig. 2 demonstrates that during the initial stage of reaction the radioactivity released is proportional to the amount of enzyme present. It should be emphasized, however, that the concentrations of mercaptoethanol and the enzyme in these experiments were lower than those used in our earlier assay method based on the measurement of ribonuclease activity[5]. Under the present conditions, the reactivation of RNase in the first 10 min of incubation was scarcely measurable. On the other hand, by elevating the mercaptoethanol and enzyme concentrations to levels where considerable reactivation occurs, the release of soluble radioactivity was practically complete within the first few minutes of incubation.

It would seem that the assay method described here is much more sensitive than the reactivation test, and its sensitivity can be further increased by decreasing the concentration of mercaptoethanol, elevating the *p*H (the optimum lies between 8·2–8·4), or extending the time of incubation. I believe, moreover, that it offers better possibilities for investigating the detailed mechanism of action, specificity, and other enzymological properties of the enzyme.

Hormone–Enzyme Complex : Insulin–Hexokinase

CORTISONE acetate dissolved in β-lipoprotein (isolated from blood plasma of normal animals) has been shown to inhibit the activity of yeast hexokinase, while on addition of insulin the inhibition is reversed, and the activity of the enzyme restored[1]. It has also been found that blocking of yeast hexokinase sulphydryl groups with parachlormercuribenzoate[2] or *N*-ethylmaleimide[3] failed to affect the activity of the enzyme. Consequently, it was obvious that sulphydryl groups of hexokinase played no part in catalysis of the glucokinase reaction[4].

The hexokinase inhibiting effect of cortisone may also be displayed when free sulphydryl groups of the enzyme are blocked, while insulin (preventing or reversing the inhibition) fails to have any effect after the sulphydryl groups become bound (Table 1).

Table 1. EFFECTS OF CORTISONE AND INSULIN ON YEAST HEXOKINASE ACTIVITY AFTER BINDING FREE SH-GROUPS OF THE ENZYME

Conditions of incubation	Hexokinase activity: Without inhibition		In the presence of *N*-ethylmaleimide (1×10^{-3} M)	
	μg P-ATP	Inhibition (per cent)	μg P-ATP	Inhibition (per cent)
No addition (control)	40	0	40	0
Added cortisone	22	45	22	45
Added insulin, followed by cortisone	40	0	—	—
Added cortisone, followed by insulin	40	0	22	45
Same + added cysteine excess	—	—	40	0

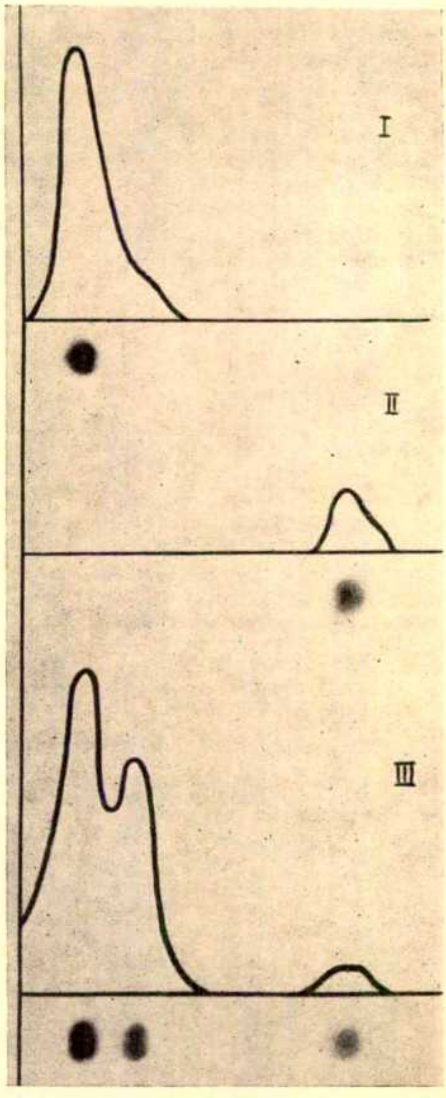
Table 2. HEXOKINASE ACTIVITY IN ELUATES FROM SPOTS ON STRIPS II AND III (FIG. 1)

Eluates from spots:	Hexokinase activity: μg P-ATP	Percentage
Strip II Hexokinase	230	100
Strip III		
(1) Hexokinase	75	32·6
(2) Insulin	0	0
(3) Third component	145	63·0
Sum of 1 + 3	220	95·6

Fig. 1 shows electrophoretograms (with corresponding 'densitograms') of crystalline insulin, crystalline hexokinase and of a mixture of them, incubated for 15 min at 37° C.

It can be seen in strip III that, in addition to the insulin and hexokinase spots, a third spot (as well as a third peak on the densitogram) has been revealed, representing a component, which exhibits reduced mobility in the electric field, as compared with hexokinase, but greater mobility than insulin.

Table 2 gives the results of an assay of hexokinase activity in eluates from the spots on strips II and III (see Fig. 1).



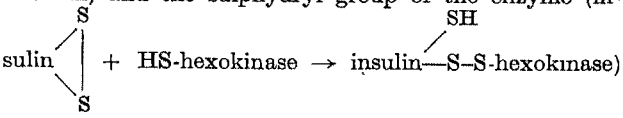


Fig. 1. Electrophoretogram (with corresponding 'densitogram'). Electrophoresis was carried out on 1·5 per cent agar gel with 0·05 M veronal buffer (*p*H 8·6). (I) 200 μg insulin; (II) 1 mg hexokinase; (III) 200 μg insulin + 1 mg hexokinase, preincubated for 15 min at 37° C

Enzymatic activity, which is absent from the hexokinase spot, has been quantitatively recovered from the spot formed by a new, third component, resulting from incubation of insulin with hexokinase (Fig. 1).

The results of this experiment demonstrate the formation of a new complex during incubation of insulin and hexokinase—a hormone–enzyme complex: insulin–hexokinase. The total hexokinase activity remained unchanged within the system. The appearance of such a complex would account for the capacity of insulin to prevent, or reverse, the inhibitory effect of cortisone on yeast hexokinase activity (Table 1).

We suggest two alternative interpretations for the mechanism of interaction between insulin and yeast hexokinase: (1) Formation of the hormone–enzyme complex insulin–hexokinase, through a disulphide bond between the –S–S– group of the hormone (probably its *A*-chain) and the sulphydryl group of the enzyme (in-

can be attributed to the action of an allosteric effector (insulin), which results in a change in the conformation of the enzymatic protein and thus its inability to interact with cortisone. (2) Fixation of insulin on the hexokinase molecule determines the capacity of the former to interact with glucocorticoid, which results in prevention of inhibition, or in liberation of the "active centre" of the enzyme when inhibition of the enzyme by the glucocorticoid occurs.

The second interpretation would seem to be similar to G. Weber's[5] views on the interaction between insulin and glucocorticoid—as revealed by its influence on hepatic glucose-6-phosphatase synthesis: repression, in the case of insulin, and reversal of the repression by glucocorticoid.

Preparation, Properties and Metabolism of Iodinated Bromosulphthalein

BROMOSULPHTHALEIN (phenoltetrabromophthalein disulphonate sodium) is metabolized by organisms and forms a conjugate with glutathione[1–4]. Rose bengal (tetrachlortetraiodofluorescein), which resembles bromosulphthalein in structure, does not form similar conjugates but undergoes partial deiodination in the organism[5–7].

While studying derivatives similar to bromosulphthalein and their metabolism we became interested in the effects of iodinating bromosulphthalein. We assumed that iodine would link to the phenolic hydroxyl in the *ortho*-position as in rose bengal.

In iodinated bromosulphthalein we expected two metabolic processes: conjugation with the sulphydryl (SH) group and deiodination.

Tubis *et al.*[8] have described the preparation and properties of iodinated bromosulphthalein. They quote an iodine content of 5·3 and 7·9 per cent in the final preparation, but this does not correspond with the required 23·2 per cent for a disubstituent. They worked with a preparation which was not precisely defined and did not investigate its metabolism. We therefore set ourselves the task of elaborating a method for the preparation of defined iodinated bromosulphthalein and of studying its metabolism.

As the initial product for the preparation of iodinated bromosulphthalein we used bromosulphthalein as prepared by Merck, *VEB*, Berlin, and also some which we prepared ourselves. 100 mg of bromosulphthalein was dissolved in 10 ml. of methanol, and 0·05 ml. of iodine monochloride was added; the mixture was heated on a boiling water bath and later 10 ml. of distilled water was added. This solution was repeatedly extracted with 25 ml. of petrol ether in order to remove the excess iodine monochloride. The aqueous solution was then evaporated to dryness on a water bath. The preparation was repeatedly recrystallized from methanol and dried for 48 h over phosphorus pentoxide in a vacuum (15 mm) and at the temperature of boiling chloroform.

The iodine content was estimated by the method developed by Schöniger[9]; it proved to be 22·5 per cent, which is in keeping with the requirement of a disubstituted derivative such as $C_{20}H_6O_{10}Br_4I_2S_2Na_2$—23·2 per cent. The spectral absorption maximum of the preparation occurred at 600 mμ and the molar extinction coefficient was 52,400. Readings were taken on a Unicam '*SP* 500' apparatus.

In a system of propanol, acetic acid and water[10] and in McMillion's system[11] the preparation was found to be chromatographically homogeneous—the R_F in the propanol system was somewhat higher than the R_F of bromosulphthalein. When we attempted a similar preparation of the dibrominated derivative of bromosulphthalein, we obtained a chromatographically heterogeneous preparation with similar properties to iodinated bromosulphthalein. It is probable that partial desulphonation had occurred as a result of the action of bromine (this is known to occur on *o*-phenol sulphonic acids[12]).

When studying the metabolism of bromosulphthalein, 5–5·5 mg/100 g body-weight of our preparation (dissolved in water) was injected intrajugularly into 24 h fasted adult Wistar rats under urethane anaesthesia. The animals were killed after 6 h by decapitation, and the small intestine was removed and divided into three equal parts, which were then rinsed in 5 ml. distilled water. The dye was only ever present in the proximal third part.

For chromatography of the content of the proximal part, a system of propanol, acetic acid and water was used, and 0·2–0·8 ml. solutions were applied to the start. The chromatographic analysis revealed that apart from free iodinated bromosulphthalein two or three other metabolites were also present. The first metabolite was blue in colour (R_F, 0·63) and occurred in the greatest concentration; the second was also blue (R_F, 0·47) but in much lower concentration than the first; and the third violet metabolite (R_F, 0·42) was present only in trace amounts which could only be detected when very large quantities of the solution were applied at the start. The third metabolite had the same R_F as one of the bromosulphthalein metabolites. Free iodinated bromosulphthalein had an R_F of 0·78 and bromosulphthalein an R_F of 0·70.

The iodinated bromosulphthalein prepared in our laboratory corresponded, from its iodine content, to a disubstituent. Although evidence is not available to say for certain whether iodination occurred in the *ortho*-position in relation to the phenol groups, we assume by analogy with rose bengal that this is so. The bromination of tetrabromophenolphthalein also occurred in the *ortho*-position to the OH phenolic groups[13]. An iodine bound in the *meta*-position would not be in line with the normal halogen substitution of the phenol nucleus which is encountered in organic chemistry[14]. The substitution of bromine for iodine in the nucleus of phthalic acid is also unlikely as the iodine content would not correspond to 23·2 per cent.

The formation of coloured metabolites from iodinated bromosulphthalein as with bromosulphthalein itself would suggest that conjugates with glutathione are also formed

similarly as with bromosulphthalein. The finding of a violet derivative, though only in minute amounts, suggests that deiodination also occurs, as the loss of iodine in the iodinated bromosulphthalein molecule would mean that there is a shift of the blue colour back to violet.

Paradoxical Influence of Calcium Ions on the Permeability of the Cell Membranes of the Isolated Rat Heart

IN the course of an investigation of the specificity of acetoacetate which causes electromechanical dissociation[1] we found that pyruvate also inhibited contractility of the rat heart and dog heart, leaving electrical activity intact[2]. Later we found that perfusion of the heart with sodium citrate caused essentially the same phenomenon. Although the inhibition of cardiac contraction by potassium citrate has already been demonstrated by Melrose *et al.*[3], it is essential to use sodium citrate in order to demonstrate electromechanical dissociation, as high potassium-levels *per se* inhibit electrical activity.

The phenomenon of electromechanical dissociation by calcium-free solutes is well established[4]; we decided to investigate whether acetoacetate, pyruvate and citrate act by lowering the available calcium of the heart cell. This possibility was strongly supported by the finding that inhibition of contractile activity by acetoacetate, pyruvate or citrate could be abolished by raising the level of calcium ions in the perfusion medium (unpublished observations).

It is well known that calcium plays an essential part in the ATP-dependent contraction-relaxation cycle of the actomyosin system; however, its influence on cell structures, such as the cell membrane, is not yet fully understood.

In the course of our investigations, we found that alterations in the calcium concentration in the perfusate give rise to large changes of membrane permeability.

This communication reports the details of our investigation.

White rats, weighing between 200 and 250 g, were anaesthetized by an intraperitoneal injection of sodium pentobarbitone. After the rats had been heparinized, their hearts were removed and perfused at 37° C using Langendorff's technique[5]. A total heart block was introduced by cutting through the bundle of His, and the hearts were electrically stimulated with a fixed frequency of 4·5 beats per sec. The procedure for simultaneous recording of the isotonic contractions and electrocardiogram has been described by Meijler *et al.*[6]. All the hearts were perfused for 30 min with the normal solution before the experiments proper were started. The effluent fluid from the hearts was collected at 1 min intervals, using a refrigerated 'Buchler'-fraction collector. The absorbancy of the effluents at 260 mμ was continuously registered.

The perfusion medium used was a modified Tyrode's solution[7]. It contained in 1 l.: 7·5 g sodium chloride; 0·35 g potassium chloride; 0·15 g calcium chloride; 1·7 g sodium bicarbonate; 0·05 g sodium dihydrogen phosphate; 0·1 g magnesium chloride; 2·0 g glucose. After gassing with a mixture of 95 per cent oxygen and 5 per cent carbon dioxide, the *p*H of the solution at 37° C was found to be 7·4; the final osmolarity was 325 mOsm. The activity of creatine phosphokinase in samples of the effluent fluid was measured spectrophotometrically at 340 mμ in cuvettes of 1 cm light path at 25° ± 2° C. In addition to 0·02 ml. of the sample, they contained 250 mM glycine buffer (*p*H 9·0), 4·2 mM magnesium chloride, 1·7 mM adenosine triphosphate (ATP), 0·13 mM phosphoenolpyruvate, 0·10 mM reduced nicotinamide-adenine dinucleotide (NADH) (except in the control), 4 μg lactate dehydrogenase, 8 μg pyruvate kinase and finally 25 mM creatine after the NADH oxidation had been registered for 10 min, so that the creatine dependent NADH oxidation could be calculated. The final volume was 1·2 ml. The activity of lactate dehydrogenase was also determined spectrophotometrically at 25° ± 2° C in the effluent fluid at 340 mμ in cuvettes containing in 1 ml.: 100 mM *tris*-hydrochloric acid (*tris*-HCl) buffer *p*H 7·6, 0·12 mM NADH (except in the control) and a sample of the heart effluent. The reaction was initiated by the addition of 5 mM pyruvate.

The enzyme activities were calculated on the basis of the initial rates of the reactions and expressed in mU (each mU denoting 1 mμmole of NADH oxidized/min). Potassium and calcium were measured by means of a flame-photometer. Adenosine diphosphate plus adenosine triphosphate were measured in some fractions by the method described by Slater[8]. Myoglobin in the effluent fluid was identified by its column chromatographical behaviour on 'DEAE-Sephadex'[9] after dialysis against 0·01 M *tris*-HCl-buffer (*p*H 8·6). Cytochrome *c* was eluted from such a column with 0·01 M *tris*-HCl, whereas the myoglobin and haemoglobin were retained at the top of the column. Myoglobin, in contrast to haemoglobin, was eluted by 0·05 M *tris*-HCl *p*H 8·6.

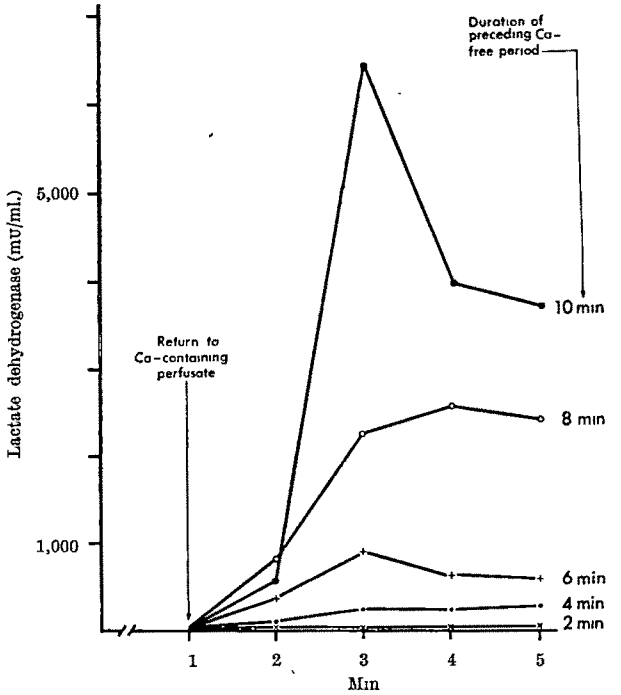

Fig. 1. Lactate dehydrogenase activity in the effluent fluid from isolated rat hearts after calcium-free perfusion for various periods of time

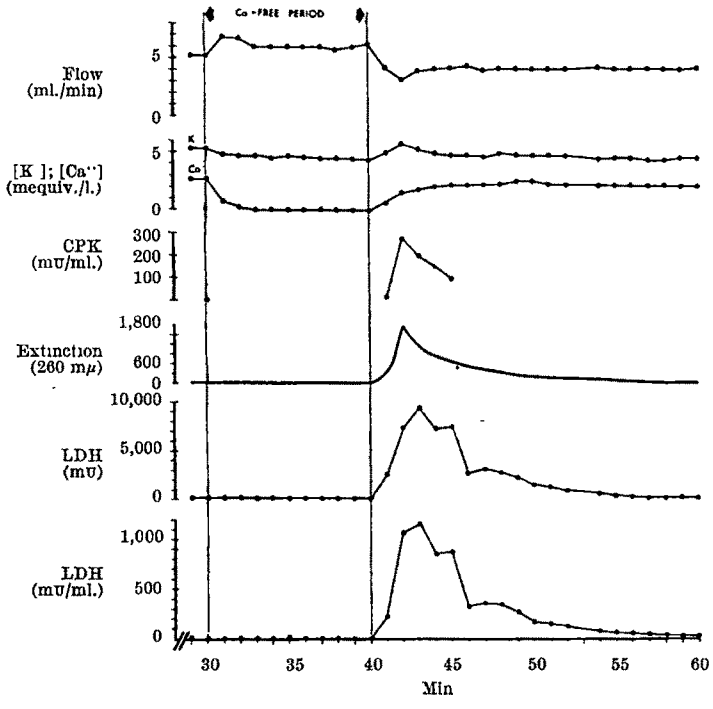

Fig. 2. Analysis of potassium- and calcium-ions, creatine phosphokinase (CPK), lactate dehydrogenase (LDH) and 260 mμ-absorbing material in the effluent of an isolated rat heart during cardiac arrest by perfusion with a calcium-free medium and the subsequent period of perfusion with a medium containing 2·6 mequiv. calcium ions. The coronary flow was calculated from the effluent fractions obtained at 1 min intervals. Total LDH activity was calculated by multiplication of the flow in ml. by the LDH activity per ml. (lower two curves)

During perfusion with a calcium-free solution it was found that contractility was abolished, but electrical activity was maintained. There was a definite increase in coronary flow. Returning to a normal perfusate after more than 2 min resulted in the disappearance of the electrocardiogram, and, after the heart had contracted a few times, these contractions passed off completely and contractile activity was not restored. The heart lost its colour and acquired a pale and mottled appearance. This phenomenon, whereby the heart maintained its red colour and electrical activity when the perfusion medium was changed from normal to calcium-free, but lost these properties on return to normal, we called the "calcium paradox". We found that the extent of these changes strongly depended on the duration of the calcium-free perfusion.

The bleaching of the hearts was accompanied by the loss of a brownish substance from the heart, which coloured the effluent yellowish-brown. A loss of myoglobin was considered to be the most likely explanation for this. This hypothesis was confirmed by measuring the absorption spectrum of the effluent. Clear peaks at 540 and 419 mμ were obtained, suggesting the loss of a haemoprotein. A spectral shift occurred after addition of dithionite. Further proof for the presence of myoglobin was obtained by chromatographic identification of the product as described earlier. No cytochrome *c* could be detected in the effluent by this method. Because myoglobin (a protein of low molecular weight) was found in the effluent, it was necessarily concluded that the calcium shift gave rise to an increase in the permeability of the cell membrane, leading to a loss of this cytoplasmic constituent. It therefore seemed of interest to investigate whether, on changing the calcium-free perfusate back to a calcium-containing perfusate, other intracellular proteins of a higher molecular weight also passed through the membrane structures. Because lactate dehydrogenase and creatine phosphokinase activities are known to be high in heart muscle, we undertook to determine whether these proteins were also present in the perfusate. It can be seen from Fig. 1 that lactate dehydrogenase indeed leaves the heart muscle after the heart has been perfused by a calcium-free solution on changing back to the calcium-containing medium. It can also be seen that the magnitude of the loss of lactate dehydrogenase is strongly dependent on the time during which the heart was perfused by the calcium-free medium. It is of interest to note that in this series of five rats, only the heart that had been perfused for 2 min with the calcium-free solution resumed its regular contractile activity after changing back to the normal perfusate. Hearts perfused for longer periods with a calcium-free solution were found to be irreversibly damaged, although a few initial contractions were observed.

Fig. 2 shows an experiment with a heart that had been perfused for 10 min with a calcium-free medium after it had been equilibrated for 30 min with normal medium. On returning to the normal perfusion medium, an almost immediate loss of lactate dehydrogenase, creatine phosphokinase, 260 mμ-absorbing material and potassium ions from the heart ensued. The correlation of these events is very striking. From the finding that the absorption at 280 mμ was about one-third of that at 260 mμ, it appeared likely that the contribution of protein to the material lost from the heart cells was relatively small. Indeed, estimation of energy-rich adenosine phosphates in the fractions with maximum 260 mμ absorption showed that at least one-third of the 260 mμ absorbing material resulted from the presence of these high-energy phosphate compounds.

We conclude from these results that, after calcium-charge, the membrane of the cell is no longer capable of retaining intracellular constituents.

We thank Prof. D. Durrer for his interest and criticism and Miss H. M. Moerdijk for technical assistance.

BIOLOGY

Distribution of Labelled Indolyl-3-acetic Acid in Intact Cucumber Plants

INDOLYL-3-ACETIC acid (IAA) applied to intact plants may induce specific morphogenetic changes, by affecting the differentiation of certain organs in those parts of the plants to which it is transported. The causal relationship between endogenous and applied growth substances and the sex expression of cucumber plants was extensively studied in this laboratory[1]. The use of radioactive IAA makes possible an accurate determination of the dis-

* IAA-2-^{14}C was injected into the petiole of the second leaf and harvested 4 or 50 h after application. Results are expressed in c.p.m. obtained in purified ether extract.

tribution and *in vivo* degradation of applied IAA. The distribution of IAA-2-^{14}C in monoecious cucumber plants was studied in order to provide data for the correlation of this distribution, with the morphogenetic effects caused by this growth substance.

A considerable amount of information exists regarding the adsorption, translocation and destruction of IAA in plant sections, but little is known about these processes in intact plants. In the present investigation, radioactive IAA was applied by several means; for example, by droplets to leaf blades, by lanoline—or polyethylene glycol ('Carbowax')—pastes applied to petioles or on stem tips, and by injection. The subsequent distribution of label was detected by autoradiographic and extraction techniques. Such tests were repeated under various environmental conditions and the auxin was applied to seedlings at different stages of development. The most uniform quantitative results were obtained when application was by means of injection. Results of a typical experiment are presented in Table 1. One μl. of solution containing 1 μg IAA-2-^{14}C (specific activity 9·2 mc./mmole) was injected into the second petiole of plants, which had developed two leaves. Ten plants were used in each treatment. After injection, the plants were left for either 4 or 50 h in the greenhouse and then appropriately sectioned. The sections were immediately killed by treatment with liquid air, freeze-dried in a Virtis 'Lyophilizator' and the dried, pulverized material was extracted three times for 1 h at 0°–1° C with a total volume of 30 ml. peroxide-free diethyl-ether. The combined ether was reduced *in vacuo* to 10 ml. and washed with 15 ml. of 0·5 M sodium bicarbonate. The sodium bicarbonate solution was acidified to *p*H 3·0–3·5 with 0·1 N hydrochloric acid and re-extracted with ether to yield the acid-neutral fraction. Radioactivity was measured by a liquid scintillation spectrometer and results were expressed in counts per minute (c.p.m.) for each plant organ.

It can be seen from Table 1 that a relatively small amount of the injected IAA was translocated away from the site of application. This would indicate that a strong limitation of IAA transport occurs in intact plants, as has been also confirmed in the coleoptiles of *Avena*[2].

The greatest accumulation of radioactivity was found in the plant apex 4 h after IAA injection. Although the stem tip is the smallest organ on a weight basis, the highest absolute amount of label was translocated to it. A comparatively minute amount of radioactivity was found in the leaves. Only about 5 per cent of the total radioactive dose injected was detected in all the plant organs 50 h after injection. This disappearance is most probably due to *in vivo* destruction. Only about half the activity detected in the purified plant extract could be identified by paper and thin-layer chromatography in the R_F region of IAA.

This rapid disappearance of IAA from intact plants is in contrast with results obtained with carbon-14-labelled 2,4-dichlorophenoxyacetic acid and other synthetic growth regulators used as herbicides[3]. It is assumed that the lack of successful recovery of IAA arises from enzymatic breakdown or conversion to other substances, most probably when growth occurs in light. It seems that endogenous IAA in the plant is much more resistant to degradation. It may be that combination with protein, with inhibitors or with other compounds provides this protection. The question as to how the application of IAA causes a marked effect on sex expression in cucumber plants[4] despite its apparent rapid degradation, however, remained unsolved.

Studies are at present being carried out, using synthetic auxin also, to gain a better insight into the processes by which auxin accumulation induces morphogenetic changes in plants.

This study was partially supported by the U.S. Department of Agriculture and carried out during the tenure of the Julius-Bär-Fellowship to one of us (J.-M. B.).

We thank Miss Rachel Dror for her technical assistance in this work.

A Self-fertile Polyhaploid Plant in an Autotetraploid Variety of Sugar Beet

A POLYHAPLOID seedling with eighteen chromosomes has been found among the offspring of cytologically controlled tetraploid plants of sugar beet. The plant survived the winter months and developed a number of seed stalks in the following spring. At flowering time the plant was isolated in a greenhouse and, in addition, one branch was bagged. Despite the fact that the original diploid variety was classified as self-sterile, the new diploid (polyhaploid) plant set a number of seeds and proved to be partially fertile[1].

Polyhaploids in autotetraploid beets were reported by Fischer[2] and Kruse[3] during investigations of polyembryony in *Beta vulgaris* L. The frequency of polyhaploids in the tetraploid beets investigated here was about one plant per thousand. If a plant such as that described here grows undetected within a tetraploid variety the consequences are obvious. While a self-sterile diploid plant in a tetraploid variety only causes the production of a certain number of triploid seeds, the self-fertile plant besides provoking aneuploidy also reproduces itself in chromosome number. Within a few generations the tetraploid variety would be invaded by plants from different chromosome levels. This emphasizes the necessity of repeated

cytological controls in autotetraploid varieties. It also indicates that polyploid material is hampered not only by chromosomal instability but also by changes at the genome level connected with unexpected genic changes.

Production of Pectic Enzymes by *Phytophthora infestans*

PECTIC enzymes have been shown to be produced *in vitro* by many plant pathogenic fungi, and evidence has been presented which suggests that they may play a part in the mechanisms of infection of the host plant[1]. Most work has been concerned with relatively non-specialized facultative parasites. Little is known about obligate parasites, for which the only record is of polygalacturonase production by germinating uredospores of *Puccinia graminis tritici*[2], and the difficulty of obtaining uredospore suspensions in axenic culture makes this work somewhat suspect. *Phytophthora infestans* shares certain features in common with obligate parasites, showing a high degree of host specificity[3], has much more exacting nutritional requirements *in vitro* than most facultative parasites[4,5], and forms haustoria[6]. The processes of germination *in vitro* appear similar to that of many obligate parasites, as zoospores readily germinate on a wide range of natural and synthetic media but do not readily continue growth to form actively growing colonies[7]. Thus the following observations on the ability of *Phytophthora infestans* to produce pectic enzymes may be of some interest.

An isolate of race 4 was grown in a range of natural and synthetic media. The basal medium contained in g/l.: potassium dihydrogen phosphate, 0·5; $MgSO_4.7H_2O$, 0·25; asparagine, 1·0; yeast extract, 5·0; thiamine, 0·001, and additions were made as shown in Table 1. The *p*H was adjusted to 5·5 before autoclaving. After 14 days' growth, the culture filtrates were tested for pectin methyl esterase (PME), exo- and endo-polymethylgalacturonase, exo- and endo-polygalacturonase[8,9], and tissue macerating activity using potato tuber disks[10]. The results are given in Table 1. A further seven isolates (two of race 4, one of race 1 and four of unknown race type) were grown in medium *F* and the culture filtrates tested for PME and macerating activity as before, and for polygalacturonase activity by the cup-plate technique[11]. Again PME was the only enzyme activity detected.

Table 1. PECTIC ENZYMES PRODUCED BY AN ISOLATE OF RACE 4

Medium	Pectic enzymes: PME	Polygalacturonase complex	Macerating activity
A 'Birds Eye' french beans	+	−	−
B Potato stems	+	−	−
C Potato tubers	+	−	−
Synthetic media (basal medium with additions as shown in g/l.)			
D Glucose 25 g	+	−	−
E Apple pectin 10 g	+	−	−
F Glucose 25 g + apple pectin 10 g	+	−	−

+, Enzyme activity demonstrated. −, No enzyme activity demonstrated.

The failure to detect polygalacturonase activity of any kind conflicts with the results of Grossmann[12], but it is possible that these are inducible enzymes only produced under conditions which were not provided in these experiments. The absence of macerating activity was not unexpected as the host's tissue is not macerated *in vivo*. Tissue disks infiltrated with culture filtrates did not go brown, and were not killed because the cells could still be plasmolysed and deplasmolysed, and so the toxicity usually associated with macerating activity was also not present[13,14]. The only enzyme activity which could be demonstrated in any filtrate was PME. This was produced in media both with and without pectin, and so behaved as a constitutive enzyme. This would suggest that it may also be produced *in vivo* and play some part in the mechanisms of infection.

I thank Prof. N. F. Robertson for his advice and the Department of Scientific and Industrial Research (now the Science Research Council) for a research studentship.

Mechanism of Fluid Exudation from Isolated Maize Roots

IT is commonly believed that salts are secreted into the xylem vessels of isolated roots by some mechanism involving metabolic energy and that the concomitant water movement is driven by the osmotic pressure gradient between xylem sap and the external medium. In particular, House and Findlay[1] have found quantitative support for this process in maize roots. These workers considered that the exudation from the basal ends of isolated roots was described by:

$$J_w = L_p RT[C_s^x - C_s^0] + \varphi_w^0 \qquad (1)$$

where J_w (cm³ exuded per cm² of root surface area per sec) is the fluid exudation rate, $L_p RT(C_s^x - C_s^0)$ is the net osmotic water flux from the external medium into the root and φ_w^0 is net water flux independent of any osmotic gradient. This latter water flow might possibly be analogous to that found in many animal epithelial preparations bathed in identical salines. In equation (1), L_p (cm/sec atm.) is the osmotic permeability or, more correctly, the hydraulic conductivity of the roots to transverse water flow, R the gas constant, T the absolute temperature, C_s^x (mole/cm³) the osmolarity of salt (for example, potassium chloride) in the exudate and C_s^0 the osmolarity of salt in the external medium. The observed difference in salt concentration ($C_s^x - C_s^0$) is likely to depend not only on the net salt flux into some compartment, like the xylem, but also on the rate of water entry into this region.

Several investigators[2-4] have proposed essentially similar descriptions of water flow to equation (1), but apparently there has been no quantitative support for this relation under steady-state conditions apart from our investigations[1]. The purpose of the experiments reported here was to test equation (1) by examining the relationship between J_w and L_p for isolated maize roots.

Grains of maize (*Zea mays*, white horse tooth) were soaked and germinated as previously described[1]. Primary roots were excised from 4- or 5-day-old seedlings which had been pretreated with a solution, π_1, containing 0·1 mM calcium chloride and 1 mM/l. potassium chloride, for 24 h before the experiment. The basal end of each root

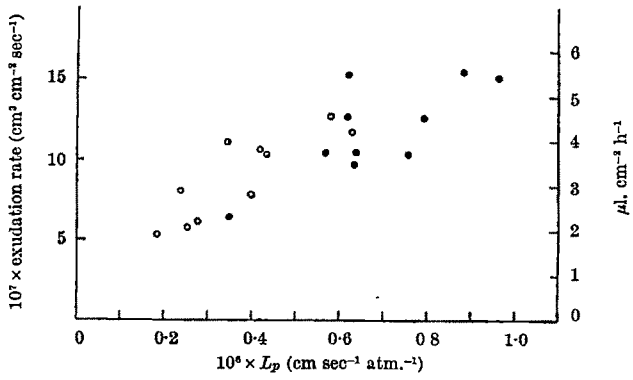

Fig. 1. The relation between the exudation rate and the estimated value of the hydraulic conductivity for isolated maize roots. Each point represents the results of an experiment on a single root. ● and ○ denote roots 5–7 cm and 9–16 cm long, respectively. The ordinate axis on the right of the figure expresses the exudation rate in conventional units

was inserted into an enlarged orifice in the end of an L-shaped glass capillary tube (internal diameter 0·05 cm) so that each root was immersed vertically in the medium. The fluid exudation rate was measured by observing the horizontal motion of the capillary meniscus with a Vernier microscope. The excised roots were 5–16 cm long and about 0·1 cm in diameter at the basal ends; the roots had no visible lateral roots or root hairs. All experiments were performed at 25° ± 1° C and under conditions of continuous aeration. For the purpose of expressing the fluid exudation rate in μl./cm² h (or cm³/cm² sec), the root surface area was assumed to be cylindrical.

After an equilibration period of at least 1 h in the basic medium, π_1, the exudation rate, $J_w{}^{\pi}{}_1$, was measured over six 5 min intervals. In every experiment, $J_w{}^{\pi}{}_1$ was constant over this period and the external medium was later replaced by a solution, π_2, containing 0·1 mM calcium chloride and 50 mM/l. potassium chloride. A rapid decrease in the exudation rate was observed and within about 150 sec the exudation had reached a minimum rate, $J_w{}^{\pi}{}_2$. Assuming that $\varphi_w{}^0$ and $C_s{}^x$ remain constant during this experiment, it is possible to show that, in these circumstances:

$$L_p = 1{\cdot}02 \times 10^4 \, (J_w{}^{\pi}{}_1 - J_w{}^{\pi}{}_2)/RT \text{ (cm/sec atm.)}$$

where RT is $2{\cdot}5 \times 10^4$ cm³ atm./mole and $J_w{}^{\pi}{}_1$ and $J_w{}^{\pi}{}_2$ are expressed in cm³/cm² sec.

Fig. 1 shows the results of these experiments on twenty roots. The mean ± *S.E.* value of L_p for roots 5–7 cm long (● in Fig. 1) was $(0{\cdot}69 \pm 0{\cdot}06) \times 10^{-6}$ cm/sec atm., while the corresponding value for roots 9–16 cm long (○ in Fig. 1) was $(0{\cdot}38 \pm 0{\cdot}05) \times 10^{-6}$ cm/sec atm. These values for L_p agree with other estimations[1] of this parameter for maize roots. Moreover, our estimates of L_p are in general agreement with those values cited by Bennet-Clark[5] for bean roots (calculated from Brouwer[6]) and by other investigators[7,8] for various plant cells and tissues. Nevertheless, a detailed discussion[9] of the experiments reported here suggests that this method of estimating L_p yields an underestimate of its actual magnitude.

Although our experiments indicate that the water permeability of the isolated maize root is not a uniform property along its length, an examination of the data in Fig. 1 showed that the relation between J_w and L_p was linear and homogeneous for the two groups of roots. Equation (1) may be considered, therefore, an adequate quantitative description of the fluid exudation from isolated roots as Fig. 1 indicates that $\varphi_w{}^0$ is non-zero; however, a satisfactory direct demonstration of the existence of $\varphi_w{}^0$ needs further investigation since there are alternative explanations[1,9] of our data.

It is concluded that the water movement in isolated maize roots is produced by an osmotic mechanism with the additional possibility that a small component of the exudation is non-osmotic in origin.

We thank the Nuffield Foundation for financial support during this work.

GENETICS

Does *Vicia faba* have Multi-stranded Chromosomes ?

THE broad bean, *Vicia faba*, has been extensively used for cytological investigations because, among others, it has the advantage of unusually large chromosomes. Several different kinds of investigation using this species have given results which suggest that its chromosomes are multi-stranded. These include autoradiographic investigations of chromosome replication[1], investigations of meiosis and mitosis following X-irradiation[2] and, most recently, direct observation of the unravelling of chromosomes following enzymatic digestion[3].

In the hemipteran tribe Pentatomini, the occurrence of species which have a tetraploid number of autosomes but DNA values like diploids[4] suggests that the latter have twice as many strands per chromosome as the former. This example illustrates the value of studying species related to those which are thought to have multi-stranded chromosomes.

We have investigated the karyotypes of *Vicia faba* and of five closely-related species of the section Euvicia of the genus *Vicia*[5]. We have modified the quantitative method for comparing karyotypes described by Martin and Hayman[6] in two ways. First, we have measured the percentage of the area of chromosome arms, rather than the percentage of their lengths, because this quantity seemed more appropriate for chromosomes which were small and, following colchicine treatment, highly contracted. Secondly, we have measured relative DNA values of mitotic root-tip nuclei isolated by the method of McLeish[7].

Vicia faba has been assigned a DNA value of 100 arbitrary units. A group of two species had 16–19 per cent of this value and a second group of three species had 50–59 per cent. Fig. 1 shows these DNA values and derived karyotypes. The percentage of area is printed against each arm, but modified (except in *V. faba*) to allow for relative DNA values. Thus in all species the areas are in the same units and are directly comparable.

The two species with low DNA values, *V. sativa* and *V. amphicarpa*, would seem to have four pairs of chromosomes in common, that is those chromosomes connected by arrows have arm areas which do not differ at the level of probability $P = 0{\cdot}05$. In the second group, the three species do not seem to share any chromosomes; however, it is not possible to distinguish with certainty four pairs of chromosomes in *V. hybrida* so that these must be grouped for statistical tests. Five similar pairs in *V. lutea* must also be grouped. When comparisons are made between these two groups, the short arms do not differ ($0{\cdot}90 > P > 0{\cdot}80$) but the long arms do ($0{\cdot}02 > P > 0{\cdot}01$), but real similarities may be obscured by the artificial grouping.

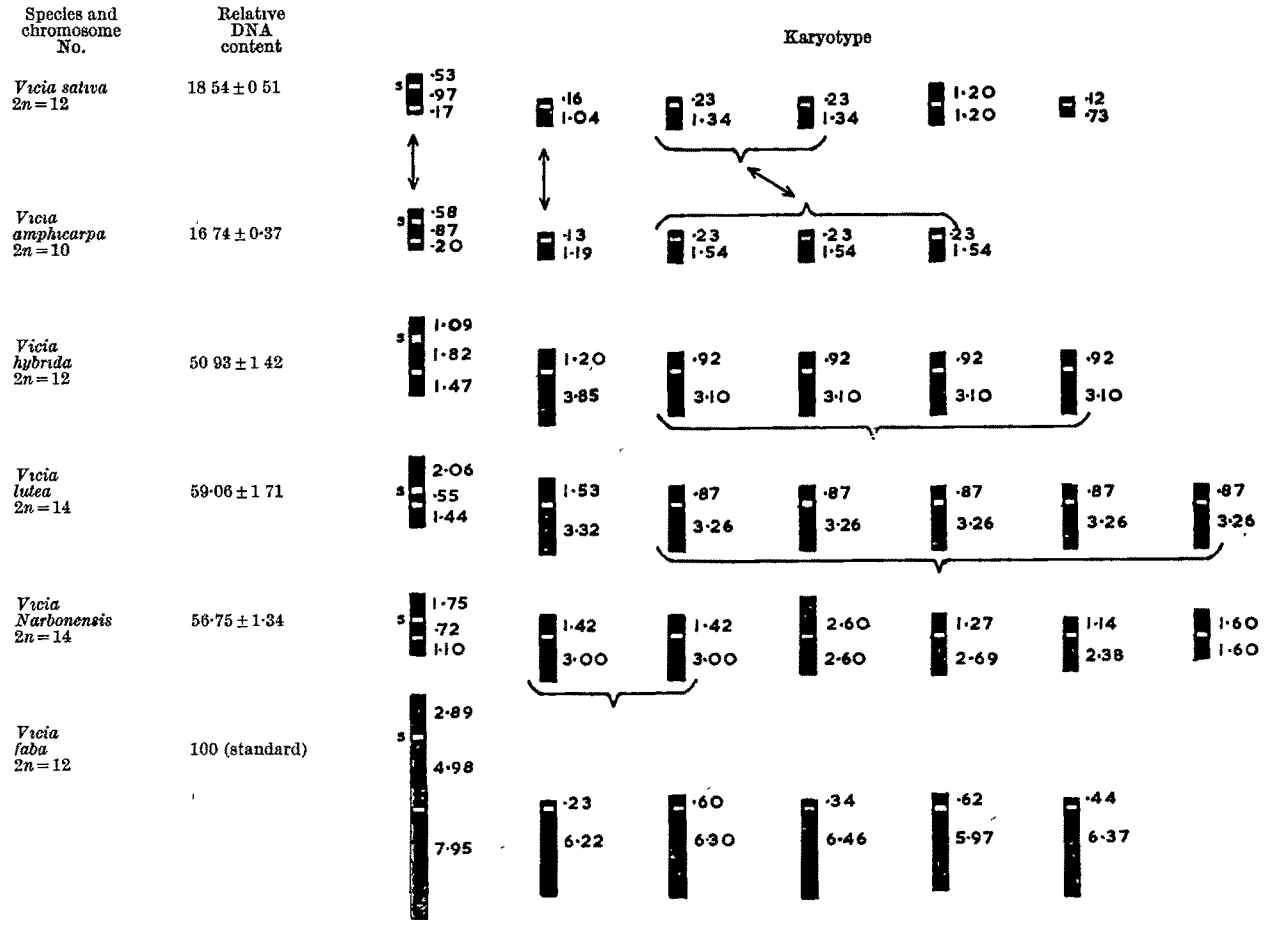

Fig. 1. Relative DNA contents and karyotypes of six species of *Vicia*. *Notes* (1) DNA values were derived from fifty cells (root-tip prophase) of both the species named and of the standard species. (2) The values alongside chromosome arms are the mean percentage of areas from photographs of twelve different cells at metaphase. Percentages are based on the diploid chromosome complement. The areas have been modified to take account of relative DNA values so that the values in different species are directly comparable. (3) Interspecific comparisons which are not significantly different are indicated by arrows. (4) *s*, Secondary constriction. (5) Chromosomes which cannot be distinguished with certainty are bracketed

The differences between the three groups of species are great and many chromosome re-arrangements are evidently involved. Unless duplications associated with re-arrangements alone can account for the large inter-group differences, it is necessary to consider the possibility that they differ in degree of polynemy. Differential polynemy has been discussed by Darlington[8] and recently reviewed by Lewis and John[9].

It has been suggested[10] that the great interspecific variation in DNA content of angiosperm nuclei is related to different adaptive values of different cell sizes. When DNA content changes by polyploidy, aneuploidy, or duplication in association with re-arrangements, advantages of changed cell size may be counteracted by disadvantages arising from reduced fertility or, except in the case of polyploidy, from genic imbalance. If changed cell size can also arise from changes in degree of polynemy, then genic imbalance should not occur; but if no disadvantages are to arise from reduced fertility, then meiosis must be able to proceed regularly. If *V. faba* does indeed have multi-stranded chromosomes, then it is able to accomplish meiosis without changing the degree of polynemy. We have found that DNA values in meiotic prophase are twice those of the preceding interphase, four times those in newly-formed pollen grains and equal to those in mitotic prophase in root-tips.

The disadvantages of multi-stranded chromosomes would be associated with hindering adaptive changes normally effected by mutation and selection. It is possibly significant that Rowlands[11] failed to detect any response to selection in *V. faba*. If it can be shown that multi-stranded chromosomes do occur in the genus *Vicia*, this may account for the comparative rareness of polyploidy in the genus[12,13]. Here the advantage of chromosome duplication would have been gained through polynemy.

The evidence discussed here suggests that different degrees of polynemy exist within the genus *Vicia*. One direct test of this would be to perform unravelling experiments similar to those of Trosko and Wolff[3]. These should reveal different numbers of strands in species from the three groups described.

Differential Response of Some Tomato Genes to Base-specific Mutagens

A NUMBER of chemicals are now known which affect specific bases of the DNA molecule[1]. These include the base analogues (such as fluorodeoxyuridine) and others like hydroxylamine and hydrazine which react mainly with cytosine and thymine respectively under particular conditions of treatment. The action of many of these chemicals on chromosomes and genes in higher organisms has not been tested extensively, but some reports are available which show that they induce localized damage in the nucleus[2–4]. We have observed a differential reaction of tomato chromosomes when pollen mother cells are treated with hydroxylamine[5]. The main finding was that a few of the chromosomes, particularly chromosome 2, were much less damaged than other members of the complement. These experiments with hydroxylamine and a number of other chemicals and X-rays have now been extended to compare the spectrum of mutations induced by them; the present communication relates to some of the results obtained.

The different treatments, details of which are presented in Table 1, were given to seeds (500 in each case) presoaked in water for various durations. The *p*H's of the freshly-prepared solutions were adjusted in a manner described elsewhere[5]. The observations on induced mutations were recorded mainly on seedlings which are easier to handle in large numbers. Also, a number of gene mutations affecting seedling characters are known to give such characteristic phenotypes that the induced variation can easily be scored for them[6].

These observations make it clear that hydrazine and hydroxylamine induce mutations at a number of loci with very different frequencies. These loci, moreover, are not randomly distributed in the genome. A number of them (*d*, *aw*, *wo*) are known to be located on one particular chromosome (chromosome 2). It should be emphasized that although hydroxylamine failed to induce mutations at these loci, the overall mutation rate with this chemical was higher than that with hydrazine, as shown by the frequency of lethal seedlings and other variation not included here because it could not easily be classified in relation to any of the known genes. Also, for comparable concentrations, hydroxylamine is found to induce significantly greater chromosomal damage and reduce germination percentage to a much greater extent (see Table 1). Ethylmethanesulphonate, which is known to react with several bases[7], differs from both in inducing chlorophyll deficiencies of various kinds, but apart from this, it appears to correspond in its action more to hydroxylamine than to hydrazine.

The observations, and the cytological analysis reported earlier, suggest that a number of loci, particularly on chromosome 2, may be characterized by an inhomogeneity in the distribution of adenine-thymine and guanine-cytosine base pairs in their DNA. Differences in base composition of this nature, if confirmed, may prove to be of considerable interest, for they may be of significance in relation to what Rick[8] has described as the asymmetrical distribution of genes on tomato chromosomes, with chromosome 2 having nearly 25 per cent of all the mapped genes located on it. No satisfactory explanation for this asymmetry has so far been available. Further analysis using techniques based on autoradiography and ultracentrifugation is in progress.

We thank Dr. M. S. Swaminathan for his kind interest in this work.

CYTOLOGY

Cytoplasmic Deoxyribonucleic Acid-containing Bodies in Amoebae

EVIDENCE has been presented, from investigations involving techniques of nuclear transfer and injections of cytoplasm, that certain cellular properties of *Amoeba proteus* and *Amoeba discoides*, such as nuclear diameter and sensitivity to streptomycin, are influenced by self-replicating cytoplasmic hereditary determinants[1–6]. The finding of DNA- and RNA-containing bodies in the cytoplasm of *Amoeba proteus*[7–9], followed by the demonstration that these bodies are self-replicating within the cell[8,9] and that they show a certain degree of interaction with the nucleus of amoeba[8], has stimulated interest in the possibility that they contain the physical basis of this cytoplasmic inheritance[6].

Cells of the strain of *Amoeba proteus*, $_{Tl}P$, and the strain of *Amoeba discoides*, $_{Tl}D$, used in the nuclear transfer

See Rick and Butler (ref. 6) for a description of the mutant phenotypes. Control mutant stocks for comparison were made available by Dr L. Butler, whose generous gifts of seeds are gratefully acknowledged.

* The simultaneous induction of these double mutants of linked genes is obviously of considerable significance.

† These variously deformed seedlings do not survive beyond the cotyledonary or 1–2 true leaf stage. A statistical analysis shows that hydroxylamine and hydrazine induce them with significantly different (1 per cent level) frequencies.

experiments[1-6] were kindly provided by Dr. S. E. Hawkins. The cells were grown in a dilute salt solution[10] at 18° C and fed daily on *Tetrahymena geleii*. Cells of both species were treated and examined in conjunction. Living cells were fixed either directly or after centrifugation at 10,000*g* for 20 min, digested with ribonuclease and stained with acridine orange[7]. Light microscope autoradiographs[7] and electron microscope autoradiographs[9] were made of cells fixed directly or after centrifugation, which had been incubated for 36 h in amoeba medium supplemented with 10 μc./ml. of tritiated thymidine (8,600 μc./μmole) (exposure was for 71 days). Normal and centrifuged cells were also fixed and stained with basic fuchsin after treatment for 7 min at 4° C with 6 per cent perchloric acid. The specificity of dyes, and of label due to incorporated tritiated thymidine, was controlled by deoxyribonuclease digestions (0·3 mg/ml. distilled water containing 10^{-3} M magnesium sulphate, adjusted to *p*H 7·0 with sodium monohydrogen phosphate, 4 h, 38° C), ribonuclease digestions (0·3 mg/ml. distilled water, adjusted to *p*H 7·0 with sodium monohydrogen phosphate, 4 h, 38° C) and treatment with 10 per cent trichloroacetic acid (TCA) at 90° C for 20 min. Controls of the digestions were prepared by incubating in similar media but with the enzymes omitted, and of the hot TCA by treatment with 10 per cent TCA at 4° C for 20 min or distilled water, 90° C for 20 min.

Examination in the fluorescence microscope of amoebae digested in ribonuclease and stained with acridine orange revealed the presence of 0·5μ–0·8μ yellowish-green bodies in the cytoplasm in the case of *A. discoides* but not *A. proteus*. In centrifuged cells of *A. discoides* the bodies were found in the region of the nucleus as described previously[7,9]. In cells stained with basic fuchsin, cytoplasmic bodies were again seen only in *A. discoides* and corresponded in size and, in centrifuged cells, in position, to those seen under the fluorescence microscope. The yellowish-green fluorescence is sensitive to DNase and removed by hot TCA, and no bodies could be found if digestion with RNase or treatment with hot TCA preceded basic fuchsin staining. In light microscope autoradiographs, about 30 per cent of the *A. proteus* cells and about 60 per cent of the *A. discoides* cells examined showed nuclear label; but stratifiable, DNase-sensitive, acid-insoluble, cytoplasmic label was found only over cells of *A. discoides*. In the electron microscope cytoplasmic bodies similar to those described previously[9] were found only in *A. discoides*, and in electron microscope autoradiographs these bodies were found to be the only entity that was significantly labelled.

In order to explain all the results of the nuclear transfer and cytoplasm transfer experiments[1-6], hereditary factors must be present in the cytoplasm of cells of both the strain of *A. discoides* and the strain of *A. proteus* used in these experiments. The present results rule out the possibility that at least in the cells of *A. proteus* the physical basis of the cytoplasmically determined differences in cell characteristics already noted is contained in the DNA- and RNA-containing bodies described by Rabinovitch, Wolstenholme and Plaut, or in similar bodies.

Two other strains of *A. proteus* (*PROT I*, and *K*) which were examined by the ribonuclease-acridine orange technique, and by basic fuchsin staining, were found to be free from the cytoplasmic bodies. The finding of strains of *A. proteus* free from cytoplasmic bodies offers a possible explanation for the single band observed in a caesium chloride gradient analysis of DNA extracted from starved amoebae[11]. As the results indicate that the cytoplasmic bodies are not an essential entity of the cytoplasm of amoeba, their suggested origin from the nucleus of amoeba[9] seems unlikely. These results tend to support the alternative hypothesis that the bodies are endosymbionts[9]. Evidence for nuclear control of the cytoplasmic bodies has already been presented[8] and, although the present results oppose the suggestion that the bodies are responsible for the cytoplasmically determined cell characterstics so far investigated, it is most probable that when present they do influence hereditary processes in the cell. As Lederberg has pointed out[12], and as has been found wherever such relationships have been thoroughly investigated, the contained organisms "comprise part of the genetic determination of the organic whole".

I thank Dr. S. E. Hawkins for cells of *Amoeba proteus* and *Amoeba discoides*, Dr. J. Griffin for *Amoeba proteus* (*PROT I*) and *Tetrahymena geleii*, and Dr. K. Holter for *Amoeba proteus* (*K* in the text). I also thank Dr. E. F. J. van Bruggen for the use of his electron microscope facilities and Prof. W. Beermann and Prof. J. A. Beardmore for constructive criticism of the text.

HAEMATOLOGY

Binding of Normal Serum Globulins to Tanned Red Blood Cells

ACCORDING to Bregman and Kirsner[1] normal human serum globulins are not usually fixed to tanned red blood cells and this is in contrast to some pathological serum globulins which have a binding capacity for these cells. These conclusions were drawn from the observation that tanned red blood cells coated with normal sera were not usually agglutinated by antiglobulin serum, whereas their coating with some pathological sera resulted in a positive Coombs's test. The difference between normal and pathological sera was even more evident when an anti-non-γ-globulin serum was applied instead of antiglobulin serum. In the anti-non-γ-globulin the anti-γ-constituent of the Coombs's serum is blocked by previous addition of γ-globulin, so that it reacts predominantly with the component of the non-γ-globulin serum[2]. In the present investigation, in which the same method was applied, evidence was obtained for the existence of an inhibitor in normal concentrated sera which interferes with the binding of the non-γ-globulin component to tanned red blood cells.

Tanning of red blood cells was effected according to the technique developed by Stavitsky[3] and a 1 : 40,000 dilution of tannic acid (Merck) in normal saline was used. 0·5 ml. of a 2·5 per cent suspension of tanned red blood cells and 1·5 ml. of the test serum serially diluted in normal saline were incubated at room temperature for 2 h. The tubes were centrifuged, and the sensitized tanned red blood cells were washed twice with normal saline and then resuspended in 0·5 ml. of normal saline.

Three millilitres of antiglobulin serum (Sevac, Prague) were repeatedly absorbed with 0·5 ml. of packed, tanned red blood cells at room temperature for 30 min, until the spontaneous agglutination with antiglobulin serum had disappeared. Anti-non-γ-globulin serum was prepared by mixing equal parts of absorbed antiglobulin serum and an 8 per cent solution of human γ-globulin (Norge).

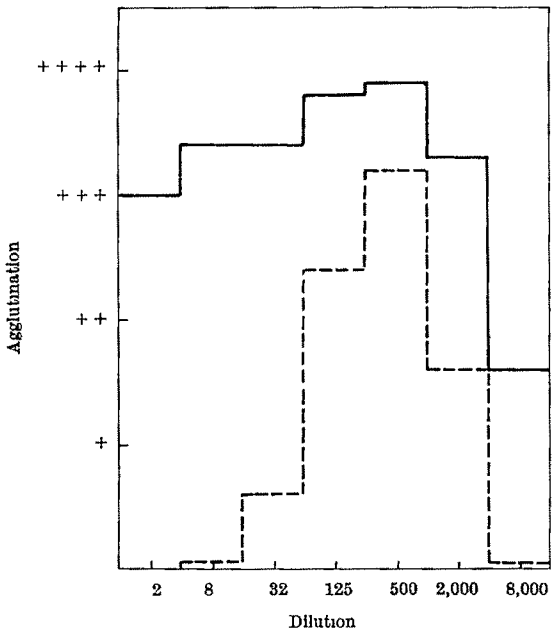

Fig. 1. Agglutination by anti-human globulin (AG) (———) and anti-non-γ-globulin (- - - -) serum of tanned human red cells coated with human normal serum (average of 16 experiments). With the anti-non-γ-globulin serum, in contrast to the antiglobulin serum, the agglutination appears only in diluted sera and is then proportional to the dilution with a maximum at 1 : 500. At all dilutions the agglutination is significantly lower with the anti-non-γ-globulin than with the antiglobulin serum ($P < 0.001$; at 1 · 500, $P = 0.01$–0.02)

Mixtures of 0·05 ml. of antiglobulin serum or anti-non-γ-globulin serum and of 0·05 ml. of the suspension of sensitized tanned red blood cells were incubated for 60 min at 37° C. The agglutination was read microscopically; its degree ranged from one to four plus. These experiments were carried out on sixteen sera.

Control experiments include: (1) tanned but uncoated red blood cells, treated with antiglobulin serum and anti-non-γ-globulin serum; (2) tanned red blood cells coated with the serum to be tested, but only washed in two changes of normal saline. In the absorption experiments carried out on five sera, 3 ml. of serum and 0·5 ml. of packed tanned red blood cells were incubated at 20° C for 30 min. After centrifugation the supernatant was separated. This procedure was repeated up to ten times.

The results are shown in Fig. 1. Tanned red blood cells sensitized with normal sera agglutinate on addition of antiglobulin serum. The degree of agglutination is higher with diluted than with concentrated sera tested. Absorption of the sera in advance by tanned red blood cells did not affect the agglutination (Table 1). Except for occasional agglutination with tanned red blood cells sensitized with concentrated sera and washed with normal saline, no agglutination was observed in other control experiments.

In contrast, the addition of anti-non-γ-globulin serum to sensitized tanned red blood cells resulted in an agglutination only with diluted sera. In concentrated sera, however, it occurred when these had been previously absorbed with tanned red blood cells (Table 1).

These phenomena would justify the assumption that both normal serum globulins and their non-γ-constituents have a binding capacity for tanned red blood cells. The binding of the non-γ-globulins, however, seems to be hindered by an inhibitor present in concentrated sera. Dilution of these sera, or their absorption with tanned red blood cells, would remove this inhibitor, the exact nature of which is as yet unknown. According to preliminary work in our laboratory it seems, however, that serum albumin might be involved in this inhibitory phenomenon.

Table 1. EFFECT OF PRIOR ABSORPTION BY TANNED RED CELLS OF A TEST SERUM ON THE DEGREE OF AGGLUTINATION

Serum dilutions		1 : 2	1 · 8	1 32	1 : 125	1 . 500
AG serum	Unabsorbed test serum	+++	++++	++++	++++	++++
	Absorbed test serum	+++	++++	++++	++++	++++
ANGG serum	Unabsorbed test serum	–	–	++	++	+++
	Absorbed test serum	+++	++	++++	+++	++

IMMUNOLOGY

Antibodies to Synthetic Corticotrophin

ADRENOCORTICOTROPHIC hormone (ACTH) is a polypeptide of particular interest as its structure is known, it has been synthesized, and the molecule has both biological and antigenic activities. In earlier publications[1,2] it was shown that antibodies to highly purified pig ACTH induced in the guinea-pig form a soluble complex with ACTH labelled with iodine-131, and that this binding is reversible.

As synthetic ACTH and its biologically active or inactive fragments have become available, it was thought that it could be used as a model for the investigation of structural features on immunogenicity and antigen–antibody interactions, and also on the relationship between biological and antigenic properties of the molecule.

The synthetic preparations of ACTH-peptides used in this investigation were: (*a*) β 1–39 ACTH, which corresponds to the natural pig full chain ACTH and has full biological activity[3]; (*b*) β 1–24, a biologically active fragment[4]; (*c*) β 1–10; and (*d*) β 11–24, fragments derived from the preparation of β 1–24 corticotrophin and without biological activity. We would like to thank Dr. R. Schwyzer, of the Department of Molecular Biology, Zurich, for the gift of these preparations.

Four groups of six to eight guinea-pigs were injected with different preparations of ACTH, as described elsewhere[2]. The guinea-pigs received five doses of 1 mg of either natural A_1 ACTH (a gift from Prof. Tausk, Organon, Oss, Holland), or synthetic β 1–39 or β 1–24 ACTH. Controls were injected with Freund's adjuvant alone.

The strengths of the antisera produced were compared by their ability to bind β 1–39-^{131}I in the radioimmunological system described previously[2]. The results shown in Fig. 1 indicate that β 1–39 was as potent in eliciting antibody formation as was the preparation of natural origin, but β 1–24 was scarcely antigenic. No binding of β 1–24-^{131}I by the sera from the guinea-pigs injected with β 1–24 could be detected, thus eliminating the possibility that such sera may contain specific antisera for β 1–24, which would not bind β 1–39-^{131}I.

Unlabelled ACTH and labelled ACTH compete for binding to antibodies against ACTH[1]. This is the basis for a radioimmunoassay. The specificity of the antibodies for ACTH can thus be examined by comparing the binding of the labelled species in the presence or absence of different unlabelled species when the antibody is at

Table 1. DISPLACEMENT OF ACTH-^{131}I FROM ANTIGEN–ANTIBODY COMPLEX BY 100 NG/ML. OF DIFFERENT PREPARATIONS OF ACTH OR FRAGMENTS OF ACTH

Preparation	Percentage of displacement
A_1 ACTH (natural, Organon)	100
β 1–39 (synthetic)	200
β 1–24	15–33 (occ. 100)
β 1–10	0
β 11–24	0·5–2

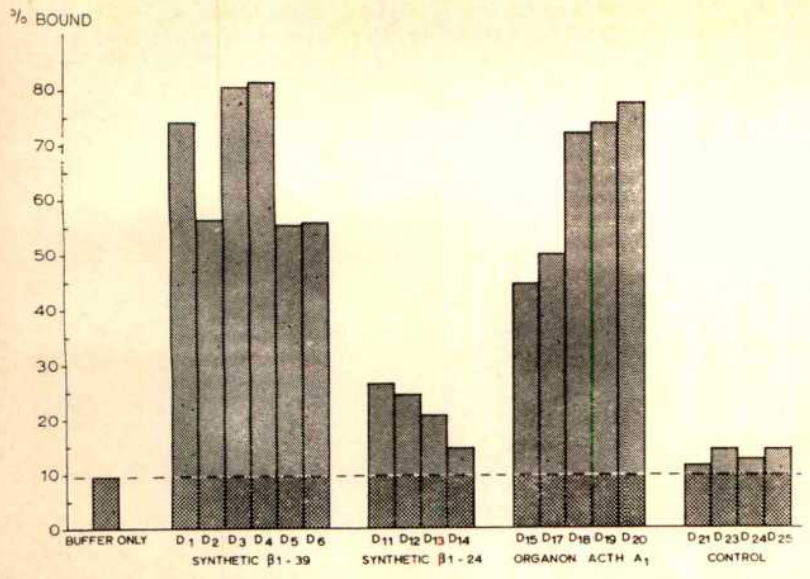

Fig. 1. Relative strengths of antisera produced by guinea-pigs against various ACTH preparations. The strengths of the antisera are expressed as the percentage binding of a fixed quantity of β 1-39-^{131}I by the same dilution (1/500) of antisera produced in a series of guinea-pigs by the injection of the preparations of ACTH shown in the figure. The control animals were injected with saline in place of hormone

such a limiting concentration that competition occurs. The results of such experiments are given in Table 1. It can be seen that β 1–24 binds to the antibodies to β 1–39, although it produces less displacement than the full chain ACTH. Smaller fragments β 1–10 and β 11–24 do not compete in any appreciable degree for the antibody sites.

The best known and best studied of the biological effects of ACTH are the adrenotropic and peripheral lipolytic activities. Lebovitz and Engel[5] have shown that the same minimum structure is necessary for both activities. In order to verify that the binding of ACTH to its antibody corresponds to a loss of the biological activity of the hormone, it was decided to investigate the effect of ACTH antiserum on the *in vitro* lipolytic activity of β 1–39 and β 1–24 synthetic corticotrophin. The method used was essentially that of Lebovitz and Engel[6], with the exception that glycerol was measured rather than FFA (free fatty acid), as glycerol is not recycled. After 1 h preincubation and 3 h incubation in 3 ml. Krebs–Ringer bicarbonate buffer containing 2 per cent albumin and the substances the effects of which on lipolysis are to be tested, the extent of lipolysis was determined by measuring the medium glycerol concentration in each flask by the method of Wieland[7]. The results (Table 2), which are expressed as micromoles glycerol/g tissue/3 h incubation, indicate the dependency of the glycerol production of epididymal fat pads on the ACTH concentrations.

The effects of antibodies on the biological activity of both the 1–39 and 1–24 polypeptides are shown in Table 3. While non-specific effects of antisera were found at low dilution, this was not the case at the dilutions used in these experiments. It is interesting to see that the antibodies obtained from guinea-pigs injected with the 1–39 synthetic peptide block the activity not only of the complete polypeptide but also of the 1–24 fragment. This finding establishes a relationship between activity inhibition and radioimmunological binding.

To sum up, these experiments show that the synthetic full chain β 1–39 ACTH is antigenic, whereas the 1–24 fragment has only little, if any, immunogenic activity. It behaves as a hapten and binds to antibodies produced against the complete ACTH chain. Binding to antibodies is followed by the loss of *in vitro* lipolytic activity of the full chain or the 1–24 fragment.

This work was supported by a grant from the Fonds National Suisse de la Recherche Scientifique.

Table 2. LIPOLYTIC EFFECT OF SYNTHETIC β 1–39

Additions to medium	μmoles glycerol/g tissue/3 h incubation
None	5·04 ± 1·61 (6)
25 ng/ml. β 1–39	8·16 ± 2·28 (6)
100 ng/ml. β 1–39	10·53 ± 2·08 (6)
250 ng/ml. β 1–39	12·83 ± 3·45 (6)

Tissues were incubated for 3 h at 37° C in Krebs-Ringer bicarbonate medium containing 2 per cent beef serum albumin in an atmosphere of 95 per cent oxygen : 5 per cent carbon dioxide. Results are expressed as the medium glycerol concentration after incubation per g tissue per 3 h of incubation and are given as mean ± standard deviation. The figures in parentheses are number of observations.

Table 3. EFFECT OF INCUBATION WITH ANTISERUM ON LIPOLYTIC ACTIVITY OF β 1–39 AND β 1–24

Additions to medium	μmoles glycerol/g tissue/3 h incubation
(*a*) β 1–39	
None	4·40 ± 0·71 (6)
100 ng/ml. β 1–39	14·20 ± 6·71 (6)
100 ng/ml. β 1–39 + antiserum 1/3,600	8·12 ± 0·90 (8)
Antiserum 1/3,600	4·59 ± 1·25 (6)
(*b*) β 1–24	
None	3·04 ± 0·57 (5)
100 ng/ml. β 1–24	8·20 ± 0·94 (8)
100 ng/ml. β 1–24 + antiserum 1/3,600	6·09 ± 0·69 (5)
Antiserum 1/3,600	3·31 ± 0·14 (4)

All media were allowed to stand at 4° C for 1 h before adding tissue. The tissue had been pre-incubated for 1 h. Incubation in the media was for 3 h. Results are expressed as the medium glycerol concentration after incubation per g tissue per 3 h incubation, and are given as mean ± standard deviation. The figures in parentheses are numbers of observations.

HISTOLOGY

Cells, Collagen Fibrils and Vessels in Dinosaur Bone

COLLAGEN has been found in mummified human remains several thousand years old, and in mastodon bones preserved under permafrost conditions. It has been stated that bone fragments after glacier preservation had all the appearances of a fresh bone[1]. Studies on Pleistocene bones have demonstrated that it is also possible to observe collagen and other organic materials in a fossil bone[2,3]. Electron micrographs of fossil bones of a deer-like animal from the Miocene (25 million years old) revealed collagen fibrils and the intact walls of canaliculi[4]. There have also been reports of striated muscle fibres, epithelial cells and melanophores being found in tissues of specimens from the Eocene (40 million years old) deposits of Geiseltal (eastern Germany)[5]. Furthermore, electron microscope investigations of patches of almost completely demineralized bone of a dinosaur from the Upper Trias

(200 million years old), and the dermal armour of Devonian ostracoderms, have revealed a fibrillar structure, while a further examination of the same material showed a mixture of mineral and collagen patterns[6]. Analysis of fishes from the Middle Devonian (380 million years old) has indicated that degradation products of collagen can still be recognized. More recently[7,8], it has been demonstrated that fossil dentine and bone-like tissues in Devonian ostracoderms can be decalcified and sectioned on a microtome. The presence in these tissues of polysaccharides as well as collagen has been indicated.

The specimen analysed and described in this communication was the phalange bone of a dinosaur from the Upper Cretaceous (80 million years old) of the Gobi Desert, Southern Mongolia. It was collected during the Polish–Mongolian Palaeontological Expedition in 1965[9].

Ground sections of the bone revealed the outlines of osteocytes, the lacunae of which were connected by numerously branched canaliculi. The lacunae were typical in shape of those present in normal bone, but varied according to the plane of cutting. By carefully decalcifying this bone material a suspension was obtained which after decantation showed elements akin to isolated osteocytes. In certain parts osteocytes were disposed longitudinally around the vessel just as in fresh bone tissue.

The same sediment was washed in Sörensen's buffer and water, and embedded in methacrylates. Sections 1-μ thick revealed the contents of the bone lacunae as well as the canaliculi together with their processes (Fig. 1).

Electron microscope examinations of the material, using the microreplica technique, revealed the presence of collagenous material in the wall of the vessel (Fig. 2). At the point indicated by the arrow, cross-banding can be seen on the surface of the fibrils with a repetition estimated to be about one every 600 Å. The electron micrograph also reveals the plaited texture of the fibrils. The specific pattern of collagen fibrils could only be determined in the wall of the vessel. This texture could not be distinguished in the fossilized element of the bone lamina, and for this reason it is assumed that the preservation of the collagen fibre may be a consequence of 'specific mummification' arising from a separation of the vessel area by a border barrier—an occurrence well known to histologists concerned with bone tissue. A similar border barrier was probably also responsible for the preservation of the structural material of the osteocytes and their processes after decalcification.

MICROBIOLOGY

Enhanced Susceptibility of Thymectomized and Irradiated Mice to Infection with *Mycobacterium leprae*

Since 1960 it has been established beyond doubt that a limited infection with the human leprosy bacillus, *Mycobacterium leprae*, can be produced in the mouse foot-pad[1,2]. Quantitative analyses have shown that the multiplication of *Myco. leprae* is limited, is dependent on the size of the inoculum and is confined to the site of inoculation. For example, inocula of 10^4 *Myco. leprae* yield 10^6 in 6–8 months, and although smaller inocula may eventually give the same yield, larger ones give no higher yields, and inocula of 10^6 or more fail to multiply significantly. Once the bacterial population in the foot-pad has reached approximately 10^6, it remains steady for many months although there is a gradual increase in the proportion of dead bacilli[2]. An identical type of limited infection has been obtained in the hamster ear and foot-pad[3,4]. Therefore, although the long-awaited successful transmission of *Myco. leprae* to animals offers for the first time an opportunity for examining human leprosy experimentally, progress in this field is now being restricted by the limited nature of the infection. One of the most likely limiting factors is an immunological one resulting from the infection. This suggestion is strengthened by the observations of Shepard[5] that prior vaccination with BCG given either locally in the foot-pad or at other sites in the body, more or less completely inhibits the multiplication of *Myco. leprae* inoculated later into the mouse foot-pad. Cortisone[6] and suramin[7,8], compounds which have been shown to enhance significantly infection with other species of mycobacteria, have no effect on infections with *Myco. leprae* in the mouse foot-pad[2,9]. On the assumption that the limiting factor has an immunological basis, an attempt to enhance the infection by prior exposure of the mice to thymectomy plus total-body irradiation was tried because of the known powerful immunological depressive effect of these combined procedures in the homograft reaction and antibody production.

Two preliminary experiments have been undertaken using twenty-four male *CBA* mice, twelve of which were thymectomized and later X-irradiated and twelve kept as untreated controls. Thymectomy was undertaken when the mice were approximately 2 months old, and 16 days later they were exposed to 900 r. and immediately afterwards transfused with bone marrow from *CBA* mice in the ratio of one donor to three recipients. Four weeks later the right hind foot-pad of each mouse was inoculated with 10^4 *Myco. leprae* (counted as acid-fast bacilli). Three groups (normal *CBA*, thymectomized-irradiated *CBA* and normal *P* strain mice) of six mice each were used for each of two strains of *Myco. leprae*. The *P* strain mice were included because our previous studies with *Myco. leprae* have been undertaken with this strain of mice. In experiment *A* the mice were inoculated with a strain of *Myco. leprae* direct from man and in experiment *B* with a first passage strain from a mouse foot-pad. One mouse from each group in the two experiments was killed at the fifth month, and thereafter at about 2-monthly intervals, and the foot-pads were homogenized to determine the total yield of acid-fast bacilli. (The methods for inoculating and collecting material from the foot-pads have already been described[2].) The proportion of degenerate (dead) *Myco. leprae* in the foot-pads at the time of harvest was determined by the method of Rees and Valentine[10]. The results of the two experiments are shown in Table 1 and Fig. 1. Comparable yields of bacilli were obtained from both strains of *Myco. leprae* in the *P* and normal *CBA* mice. In both experiments the infection was enhanced in the thymectomized-irradiated *CBA* mice resulting in significantly higher yields of bacilli which continued to increase for a longer period with a lower proportion of degenerate bacilli than in the normal *CBA* mice. In experiments *A* and *B* there were, respectively, about ten and a hundred times greater yields of bacilli in the thymec-

Table 1. Yield and Proportion of Degenerate Bacteria in the Foot-pads of Thymectomized-irradiated *CBA* and Normal *CBA* and *P* Strain Mice Inoculated with 10^4 new (*A*) or Passage Strain (*B*) of *Myco. leprae*

tomized-irradiated than in the normal *CBA* mice. On the other hand, there was no evidence of systemic spread of the infection in the thymectomized-irradiated mice as no acid-fast bacilli were seen in Ziehl-Neelsen stained impression smears from the livers and spleens, and only one inguinal lymph node showed a few bacilli. Bacilli recovered from thymectomized-irradiated mice (designated "*I*" in Table 1), when passaged to normal *P* or *CBA* strains of mice, reverted to infections yielding not more than 10^6 bacilli/foot-pad. Finally, while histological examination of the foot-pad of one thymectomized-irradiated mouse killed at 8 months revealed a large number of bacilli, the organisms were for the most found within striated muscle fibres, which is the characteristic distribution observed in normal mice[11].

It is reasonable to conclude from these preliminary investigations that at least one factor limiting multiplication of *Myco. leprae* in the mouse foot-pad is the development of immunity during the course of infection. This conclusion is strengthened by the reports that bacterial[12] and viral[13] infections are enhanced by thymectomy in rats and mice, respectively. Furthermore, it has been demonstrated that the post-neonatal thymectomy wasting syndrome is almost certainly based on an infectious aetiology since the syndrome does not occur in thymectomized germ-free animals[14]. These studies have particular interest because they represent the first deliberate attempt to use thymectomy plus irradiation for increasing the susceptibility of animals to chronic infections. However, the impaired immune response following thymectomy plus irradiation still resulted in only limited multiplication of *Myco. leprae*, albeit at a ten to a hundred times higher level than obtained in normal mice, and there was no spread of infection beyond the foot-pad. Failure to obtain under these conditions a completely progressive infection with systemic spread may be comparable with the similar significant, but only partial, depression of the ability of thymectomized-irradiated mice to reject the more foreign skin grafts[15]. In order to demonstrate beyond doubt an immunological basis for the enhanced infection following thymectomy plus irradiation, it will be necessary to show that the enhancement can be neutralized by lymphocyte replacement. Because only a partial enhancement of infection has been obtained it is not possible to exclude other limiting factors.

Thus thymectomy plus irradiation already provides a means for significantly increasing the yield of *Myco. leprae* in the mouse foot-pad infection. Further experiments must be undertaken to determine whether similar treatment will sufficiently diminish the resistance of animals to allow larger inocula (not less than 10^6 bacilli/foot-pad) to multiply or to allow intravenous inocula to multiply systemically.

I thank Dr. R. B. Taylor for performing the thymectomies and for his advice and guidance.

Antagonism between Vegetative Cells and *L*-Forms of *Bacillus licheniformis* Strain 6346

Landman and Halle[1] showed that lysozyme or penicillin in suitable circumstances could cause mass conversion of vegetative cells of *Bacillus subtilis* strain 168 (indole⁻) to *L*-forms. These *L*-forms could be sub-cultured on so-called "*S.D.*" medium which contains glucose salts, horse serum, sodium succinate and tryptophan, with 0·9 per cent agar. Prolonged incubation (5–10 days) on the normal medium (*S.D.*) or short incubation (48 h) on media with an increased concentration of agar led to equally massive reversion of the *L*-forms back to bacteria. Later[2] the conversion to *L*-forms of both *B. subtilis* and *B. licheniformis* was shown to be accompanied by the extrusion of mesosomes. The authors comment that "Our data on the stimulation of reversion by physical agents have suggested . . . that membrane invagination may be the primary event".

In the present work *L*-forms of *B. licheniformis* strain 6346 were made[1] with 500 μg/ml. benzylpenicillin (they could also be made with *cyclo*serine or methicillin). After conversion to *L*-forms a block of agar containing one colony was streaked on to *S.D.* medium containing 500 μg/ml. benzylpenicillin. Ten successive sub-cultures were made on the same medium and the *L*-forms were then transferred to medium not containing penicillin, and 100 per cent reverted to the bacillary form during 48 h. All incubations were at 35° C. After the thirtieth passage on penicillin media, however, the reversion in the absence of the antibiotic was lower and delayed and, starting from the thirtieth passage, sub-culture was made on penicillin-free media. After the fiftieth passage there was no detectable reversion to bacterial forms, that is to say, the *L* strain appeared to be stable. When the agar concentra-

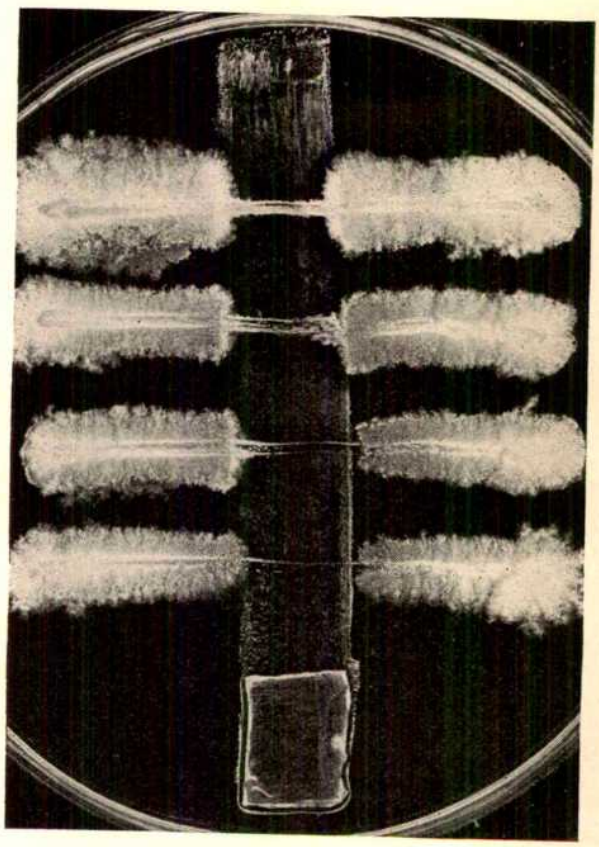

Fig. 1. An *S.D.* agar plate was streaked in the vertical direction with *L*-forms and at right angles with decreasing (from top to bottom) amounts of an *S.D.* liquid culture of vegetative cells of *B. licheniformis* 6346. Clear zones of inhibition both of bacterial and *L*-form growth can be seen

tion in the *S.D.* medium was increased to 2·5 per cent a considerable number of revertants appeared after 48 h growth. The amount of growth of *L*-forms was considerably less on this medium. It seemed that partial inhibition of *L*-form growth occurred; if there were any antagonism between growth of *L*-forms and of bacilli it could well explain the more frequent emergence of revertant colonies.

A plate of *S.D.* agar was first streaked in one direction with a block of agar cut from an *L*-form culture grown on the same medium, and then an overnight culture of the parent bacillus in fluid *S.D.* medium was streaked at right angles to the tracks of the block of agar containing the *L*-forms. The test was also made on other plates with fluid cultures of ten revertants. The plates were incubated at 35° C for 24, 48 and 72 h. Zones of inhibition of the vegetative cells and of the *L*-forms were always seen. Fig. 1 is a photograph of a plate that had been incubated for 72 h. The antagonism demonstrated in Fig. 1 could account for the failure to detect revertants on ordinary *S.D.* agar, when the good growth of *L*-forms would be expected to inhibit the emergence of colonies of revertant bacilli. The higher agar concentration which depresses the growth of the *L*-form may allow the growth of the revertant bacteria into detectable colonies.

Preliminary work has been done on the nature of the inhibition of the growth of *L*-forms by the bacilli. Cultures of *Bacillus licheniformis* 6346, growing on *S.D.* agar medium, were extracted by freezing and thawing, and the extract was shown to be inhibitory to the growth of *L*-forms. The substance is heat-labile and non-dialysable; it could not be detected either in disrupted cells or in the culture fluid from cultures of *B. licheniformis* 6346 grown in fluid *S.D.* medium for 24 h.

Flagella-assisted Cell Fission in *Escherichia coli*

Hoffman and Frank[1] have recently described what they call "snapping movements" during division of *Escherichia coli*. The evidence presented consists of "a time-lapse series of four photomicrographs . . . inadvertently obtained from a microculture of *E. coli* during the snapping of a cell pair". The whole snapping sequence appears to have taken about one minute seventeen seconds, and is described as follows: "The sister cell on the right side of the photomicrograph (Fig. 2) exhibits a blurring interpreted as owing to a vibrating motion of the cell with its proximal end acting as a moving pivot. The proximal end of the second cell is slightly blurred from movement as well, indicating cell flexion with the midpoint of the cells as the pivot. The right-hand cell at one point during these movements seems to have paused in the long axis of its sister for an appreciable time, since its photographic image in this position is more fully developed than in any other. Fig. 3, photographed at one minute nine seconds from zero-time, indicates continued back and forth motion which was followed by a sudden large hinge movement of the cell in a counterclockwise direction, and a consequent decrease in the obtuseness of the angle formed with its sister . . . ".

The phenomenon described by Hoffman and Frank is not uncommon in *E. coli*, ("an organism not thought to be capable of this manoeuvre") if the right strain is observed under appropriate conditions. During the course of several years study of division in *E. coli* (for methods see ref. 2) several strains were observed in continuous flow microculture which allowed the behaviour during division of motile strains to be clearly observed. What occurs is exemplified by the following experiment within the Fredericq strain *CA* 18.

The organism was grown on nutrient agar for about 20 h at 37° C and some of the growth washed off with 0·5 ml. synthetic medium, mixed with about 5 ml. of synthetic medium and a droplet inoculated onto the prepared membrane of the continuous culture chamber through which a flow of synthetic medium was maintained. Motility was not observed during the first 2·75 h. The inoculum cells settled onto the membrane and remained quite still until the movements described. The division history of five cells (*a–e*) continuously observed for 4 h was as follows. The membrane was inoculated at 11.00 a.m.; at 11.30 a.m. cell *a* divided and the sister offspring (a_1 and a_2) remained non-motile and continued to grow slowly. At 2.10 p.m. cell wall fission of one of these offspring, a_1, appeared to be complete and at about the same time a rotary vibratory motion started at one end of the couplet (with the other apparently firmly adherent to the membrane), which continued intermittently for 3 min when the distal cell broke away abruptly and immediately swam rapidly out of the field of view. The cell remaining behind from this fission was motionless for about 15 min and then began vibrating in the way its partner had done—the vibrating end was the newly formed "fission wall". This would suggest that in this strain the generation of functional flagella under the conditions of culture required 15 min. The first generation cell a_2 divided at 2.25 p.m. and one of the offspring, as before, commenced flagellar lashing at its extremity which proceeded actively with occasional pauses for 'rest' during the next 10 min. For the following 15 min lashing continued with diminishing energy and longer pauses and ceased altogether at 2.40 p.m. when the pair remained at rest (in the relative positions shown in Fig. 1) up to the termination of the experiment, at 3.00 p.m. It would seem that this cell "burnt-out" its energy without achieving a complete "break-away" from its partner (connected probably by capsular material as the walls were obviously separate).

Cell *b* divided at 11.50 a.m. and one partner moved dispiritedly during the course of 5 min, the pair coming to rest side by side as shown in Fig. 1 with no further movement and apparently no growth until 3.00 p.m. These cells were in all probability non-viable. Cell *c* divided at 2.02 p.m. accompanied by flagellar lashing for 8 min when break-away was achieved. Similarly, cell *d* divided at 2.40 p.m. accompanied by lashing until 2.48 p.m., when the motile sister broke away and immediately swam hastily out of the field of observation. Cell *e* divided at 2.45 p.m. only 15 min before break-down of the experiment with weak lashing movement, but the sisters were still apparently adherent when observation ceased.

In addition to these cell movements, from about 2.00 p.m. motile cells were seen to swim actively across the field of view. By 2.30 p.m. the number of motile cells had significantly increased and by 2.45 p.m. about four cells per minute were crossing the field of view. A high proportion of the swimming cells were unseparated couplets which showed a distinctive mode of propulsion which provided the basis for belief that the movements described were caused by flagella. Each couplet had a more or less static leading cell while the trailing propulsive cell showed vigorous rotary gyration in an anticlockwise sense viewed from the rear (Fig. 2), which caused the

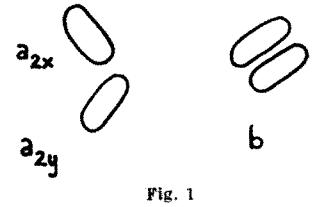

Fig. 1

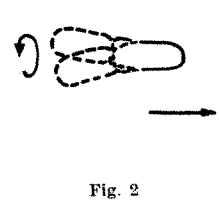

Fig. 2

couplet to move forward so that any point on the surface of the leading cell traced out a helical path.

Hoffman and Frank discount the possibility that snapping movements are due to the action of flagella, which is strange when they claim to have worked with a motile strain and also state that the phenomenon was observed only in the transitional zone of the micro-culture system used[3] where there would be the necessary freedom of movement. In my own experiments there was complete facility for free-swimming as there was no pressure between membrane and cover-slip. Also, the four photomicrographs published might be misleading as problems of depth-of-focus would necessarily dictate that images were obtained only in one plane so that rotary action could not be recorded. Yet none of the recordings of these authors contradict the findings made by direct continuous observation, and are, in fact, wholly compatible with them, even in regard to the periods of rest during lashing activity which is recorded micrographically by the non-blurred image published in Fig. 4 of Hoffman and Frank's paper.

The reported observations would seem to indicate that the flagellation in this strain might be polar, yet Leifson[4] reports that of several dozen strains of *E. coli* examined all were peritrichously flagellate, although some had very few flagella; moreover, these observations on motility fully confirm other well-established views (see Weibull[5]), but we have yet to understand how peritrichously arranged flagella could drive bacteria in the unidirectional manner observed.

Hydrocarbons as Substrates for Yeasts

Markovetz and Kallio[1] pointed out that the assimilation of hydrocarbons might be of value in the classification of yeasts. Komagata *et al.*[2] found that fifty-six of 498 yeast strains belonging to twenty-eight genera were able to grow on kerosene as the sole source of carbon and energy. All strains except two belonged to the genus *Candida*. In several species some strains grew well on kerosene, while others did not. No growth on kerosene was observed with some species, which were able to assimilate pure hydrocarbons of the kerosene fraction according to other reports[1,3].

We investigated whether the results for the assimilation of *n*-decane and *n*-hexadecane by various yeast species correspond with those on kerosene and, furthermore, whether the utilization of these hydrocarbons may be a specific property of the species. We tested 1,200 yeast strains of the culture collection of the Centraalbureau voor Schimmelcultures. The 244 species represented by these strains belonged to the following genera: *Saccharomyces* (thirty-seven), *Hansenula* (twenty-one), *Pichia* (thirty), *Debaryomyces* (ten), *Candida* (fifty-four), *Torulopsis* (fifty-two), *Brettanomyces* (seven), *Kloeckera* (eight), *Cryptococcus* (ten) and *Rhodotorula* (fifteen).

For the preliminary screening reported here the technique of replica-plating was applied. Thirty cultures were transferred to the initial plate, containing wort agar, and incubated at 25° C for 2 days. The basic medium for the tests was a mineral agar with B-vitamins[4].

To the sterilized basal agar, in which 0·25 per cent taurocholate was incorporated for better emulgation, 1 per cent *n*-hexadecane (99 per cent pure, Fluka) was added. *n*-Decane (99 per cent pure, Fluka) and kerosene (normal Esso) were supplied as vapour. The plates were incubated at 25° C for 1 week. If strains of a species grew both on *n*-decane and *n*-hexadecane as well as on kerosene, one of these strains was retested in shaken cultures with 2 per cent of the same carbon sources.

Table 1. NUMBER OF STRAINS ASSIMILATING *n*-HEXADECANE, *n*-DECANE AND KEROSENE IN SOME SPECIES OF *Pichia*, *Debaryomyces*, *Torulopsis* AND *Candida*

Species	Number of strains tested	Number of strains growing on *n*-Hexadecane	*n*-Decane	Kerosene
**Pichia farinosa*	22	22	22	19

Candida tropicalis	24	24	24	24

* Species not previously known as hydrocarbon utilizers.

In the genus *Kloeckera* no *n*-decane, *n*-hexadecane and kerosene assimilating strains were detected. A few of the *Hansenula*, *Brettanomyces* and *Cryptococcus* strains grew very weakly on *n*-hexadecane. In the genus *Saccharomyces* only the two strains of *Saccharomyces elongasporus* assimilated hydrocarbons readily, but the yeast differs from the typical species of this genus by a slow fermentation and the shape of the spores. In some *Rhodotorula* species *n*-decane-, *n*-hexadecane- and kerosene-utilizing strains occurred, but growth was very slow or weak; negative strains were found in the same species. Many strains, utilizing *n*-decane, *n*-hexadecane and kerosene, were detected in the genera *Pichia*, *Debaryomyces*, *Candida* and *Torulopsis*. Some of the results are shown in Table 1. The species not previously known as hydrocarbon utilizers are indicated by an asterisk.

Generally, growth on kerosene vapour was weaker than on the pure *n*-alkanes; sometimes no growth on kerosene was observed with strains assimilating *n*-decane and *n*-hexadecane. Some strains, which grew well on kerosene vapour, failed to grow in shaken cultures containing kerosene. This suggests that the absence of growth may be due to an inhibitory effect of some components of the kerosene, rather than to the inability of the yeast to attack the *n*-alkanes. The results with the shaken cultures containing *n*-decane and *n*-hexadecane paralleled those obtained on agar, but in liquid medium growth was often better with *n*-hexadecane. In many species all strains utilized the pure *n*-alkanes, indicating that this ability can be a characteristic feature of the species. However, the assimilation of *n*-alkanes by the strains of one species may vary from weak or latent to good. In species, where only some strains were found to assimilate *n*-alkanes, growth was generally poor.

Additional strains utilizing *n*-alkanes could probably be detected with test conditions more favourable to adaptation and selection.

RADIOBIOLOGY

A Computer Programme for Automatic Scanning of Autoradiographs and Microradiographs of Bone Sections

AUTORADIOGRAPHY of bone has played an important part in the investigation of the distribution of bone-seeking isotopes. A measure of the non-uniformity of this distribution is of paramount importance in determining local radiation doses in bone and adjacent soft tissues. In addition, a comparison of autoradiographic and microradiographic pictures can provide information about bone resorption and bone turnover. Until recently these measurements have been severely limited in scope because of the tedious and time-consuming nature of such analyses. With advances in automatic densitometry and computers, these analyses have now become practicable on a much wider scale.

This report outlines the use of an automatic scanner under the control of a computer which is capable of analysing the distribution and area of blackening on a photographic film. The machine (named *Chloe*) was designed and built for the analysis of spark chamber photographs[1] and pattern recognition of chromosomes[2]. In the present application, a spot of light from a cathode-ray tube is focused on to the autoradiographic plate and the light transmitted through the plate is viewed by a photomultiplier. This light spot ($\sim 15\mu$ in diameter) is driven in both the X and Y direction by two counting registers so as to scan a rectangular area on the plate, the extent of which is determined by the computer programme. The spot does not actually move, but appears in one place for 1 μsec, is blanked out for 3 μsec, and reappears in the adjacent location for 1 μsec. When the photomultiplier detects less than a specified amount of transmitted light, the contents of the registers are entered into the computer memory as the co-ordinates of the point. The beam then moves on until the photomultiplier again detects more than the given amount of light and the co-ordinates of this second point are entered in memory. These two points determine a line segment. Overlapping line segments are later assembled into shapes by the computer programme.

The calibration and stabilization of beam intensity in terms of photographic density are of the utmost importance in the operation of the scanner as an automatic densitometer. Calibration plates are therefore used to act as calibrators both for area and for density. A step wedge containing fifteen steps ranging in density from 0·05 to 2·1 was constructed to fill the scanning area, which was 1 in.^{2} on the photographic plate. The portions of this plate transmitting less light than that corresponding to a fixed photomultiplier discriminator setting were displayed on a separate cathode-ray tube. Beam intensity values corresponding to each density level on the step wedge were determined by increasing the cathode ray beam current in small discrete increments until the apparent area of each step was reduced by half. This information provided a table of beam intensity versus density which was later fed into the computer memory. All beam intensities are corrected for the background blackening of each plate by an automatic background measurement.

A further calibration plate with two spots of known density and a third black spot of known area is inserted in the scanner before each data plate in order to correct for any change in the operating conditions. The computer measures these two densities automatically, compares them with their known values, computes a quadratic correction function, and substitutes a corrected table of net beam intensity versus density into its memory.

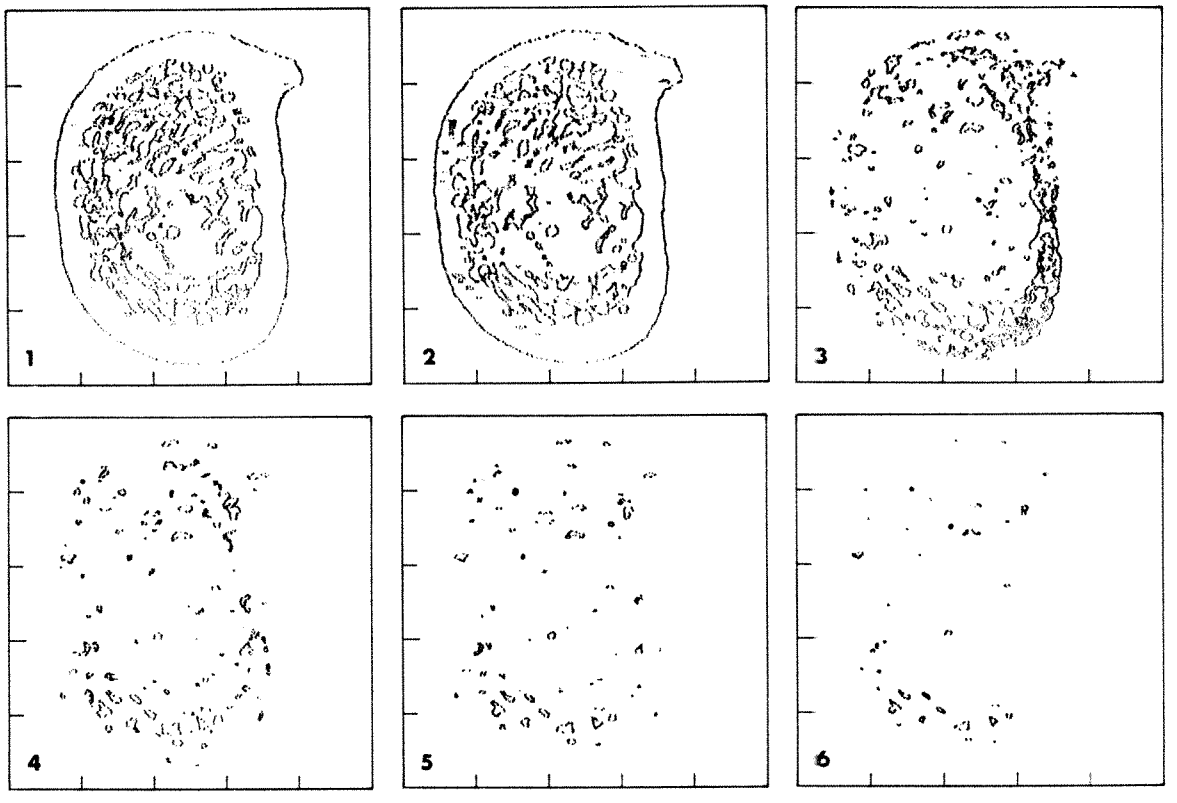

Fig. 1. Pictures, reconstituted from digital information using a *Calcomp* plotting device. Isodensity lines are drawn to indicate areas of the autoradiograph which fall above a certain level of photographic density. The six pictures correspond to six different density levels in steps of 0·08 from picture (1) corresponding to density 0·08 to picture (6) corresponding to density 0·48

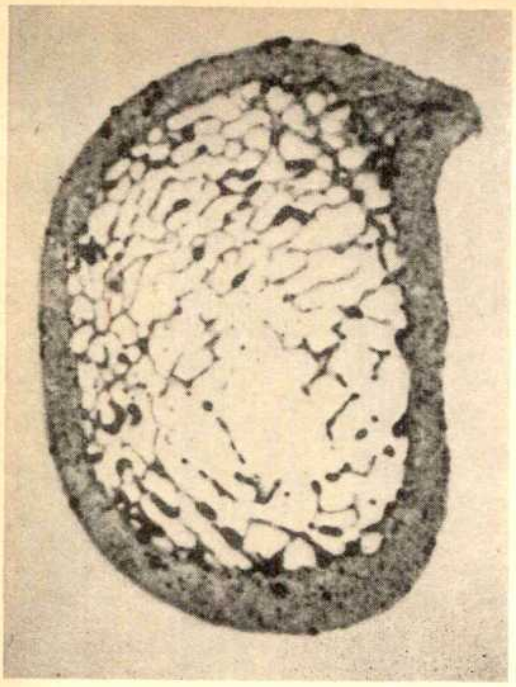

Fig. 2. Autoradiograph of a cross-section of bone taken from the distal femur of an adult dog injected with 500 μc./kg of calcium-45 and killed 17 days later

So far, the computer has been programmed to read-out areas and shapes corresponding to different photographic densities. This information is stored on magnetic tape and the corresponding areas and densities are available in a print-out form. To test the procedure, the autoradiograph can be reconstructed from computer memory to show isodensity lines in the form of pictures. These are shown in Fig. 1, the autoradiograph in Fig. 2.

Other forms of output, such as read-out in terms of isotope concentration in microscopic areas on the autoradiograph, can be obtained by inserting a calibration of the isotope in the form of a radiator on the same photographic plate as the bone section. Investigation of microradiographs to obtain quantitative information such as bone porosity is also possible with the present programme.

Other investigations for which this scanning equipment may prove useful are: (1) investigations of changing distribution of isotopes either as a function of time after administration in animal experiments or as altered by external factors such as drugs; (2) mineral density measurements using microradiography; (3) correlation of autoradiographic and microradiographic pictures of the same bone section to give information on bone resorption. These are just a few of the possible applications of this automatic scanning device to problems associated with bone. However, the scanner described here has basically been designed as an automatic densitometer and it may prove useful in fields of research other than just those pertaining to bone.

This work was performed under the auspices of the U.S. Atomic Energy Commission.

Radiation Recovery Response of Mammalian Tumour Cells *in vivo*

SINCE the original report by Elkind and Sutton[1] that mammalian cells are able to repair sublethal radiation damage *in vitro*, there have been several reports describing similar results in a variety of mammalian cell systems both *in vitro* and *in vivo*[2]. The *P*-388 murine lymphocytic leukaemia maintained as an ascites tumour in the *DBA*/2 mouse is ideal material with which to investigate the recovery response of a malignant mammalian cell *in vivo*. Shortly after intraperitoneal transplantation of 10^6 cells (24–48 h), the radiation response of this tumour is typical for that of an oxygenated population; after 6–7 days of intraperitoneal growth, this tumour demonstrates anoxic radiation response[3]. Consequently, it is possible to investigate the radiation recovery response of oxygenated and hypoxic cells depending on the age of the tumour at the time of the conditioning dose. Fig. 1 shows the survival response for 1-day tumours and 6-day tumours irradiated *in vivo* and assayed for tumour cell viability as previously described[3]. The dose modifying factor for 6-day tumours with respect to 1-day tumours is ~3. In addition, while both curves have an initial shoulder, the extrapolation number for 1-day cells is significantly higher than that for 6-day cells.

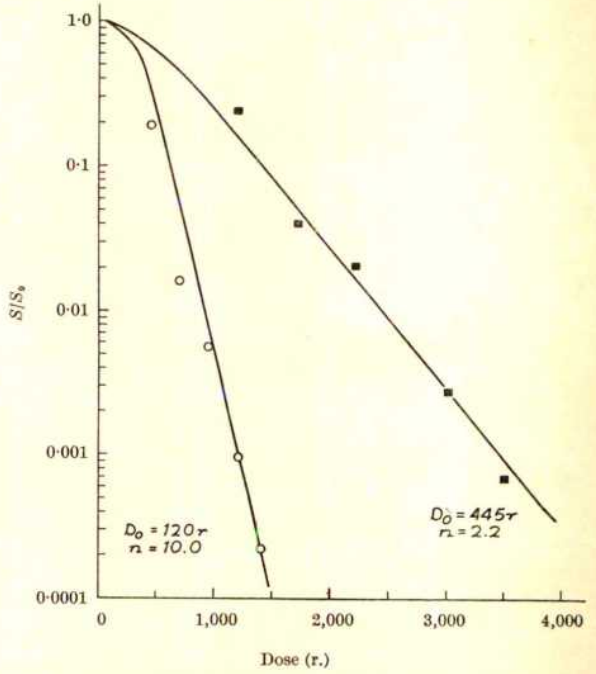

Fig. 1. Survival curves for *P*-388 tumours irradiated and assayed *in vivo*. 1-day tumours (○) and 6-day tumours (■). *n*, Extrapolation number; D_0, dose in roentgens required to reduce the surviving fraction to 1/*e* on the exponential portion of the curve. 6-day tumours are more radio-resistant by a factor of 3·7

A series of experiments was undertaken designed to investigate the radiation recovery response of *P*-388 tumour as a function of tumour-age at the time of the conditioning dose. Animals bearing 1-day or 6-day tumours were irradiated with whole-body air exposure doses of 500 r. or 1,500 r. respectively, at time 0. At intervals of time up to 14 h following this conditioning dose, a second, equal dose was delivered to the same animals. X-radiation was produced at 220 kV, 18 m.amp and 0·5 mm copper and 1·0 mm aluminium filtration (half value layer 1·33 mm copper), and this gave 212 r./min at a target–surface distance of 25 cm. Immediately after the second dose, cells were removed from the abdomen and assayed for reproductive viability; recipient animals

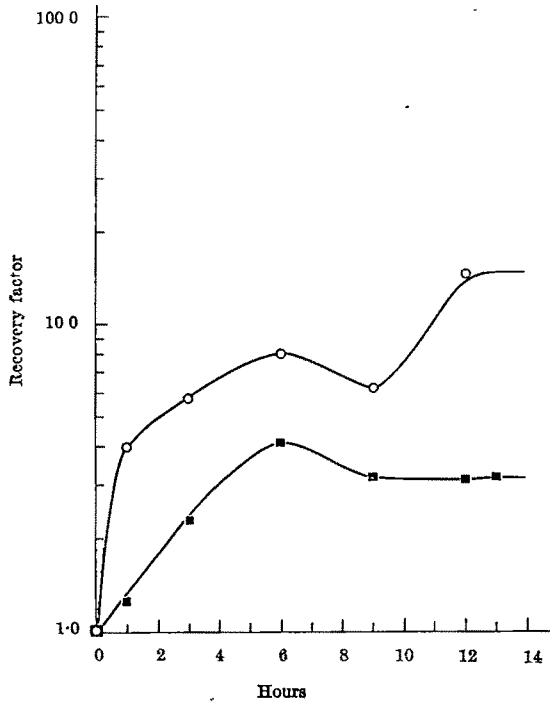

Fig. 2. Recovery response of 6-day tumours (■) and 1-day tumours (○). Recovery factor is the observed survival fraction to two-dose fractions relative to the total dose delivered in one exposure

were inspected for tumour formation and such tumour production data were analysed as described by Belli and Andrews[3].

Net survival fractions to the fractionated dose were expressed relative to the survival fraction which resulted from the total dose without fractionation (recovery factor). A recovery factor of 1·0 indicates no recovery. These data are given in Fig. 2. Initial, rapid repair of sublethal damage is evident in tumours of either age. However, the rate of repair seems to be slower in 6-day (hypoxic) tumours. Initial repair appears to reach a maximum by 6 h following the conditioning dose in both tumours. A subsequent minimum is seen at 9 h which rises to a second maximum by 12 h in 1-day tumours. In the hypoxic condition, however, this minimum appears to persist through 13 h. It is of interest to note that the maximum recovery factor for 1-day tumours (~ 15) and for 6-day tumours (~ 4) are of the same order of magnitude as the extrapolation numbers observed from the acute exposure survival curve for these tumours (ten and two respectively).

The data reported here demonstrate that mammalian tumour cells are capable of repairing sublethal radiation damage *in vivo* regardless of whether the cell is aerobic or hypoxic at the time of the first dose, but that the rate of repair is probably influenced by the state of oxygenation of the tumour cell population at the time of conditioning dose. These data are also compatible with the model first proposed by Elkind *et al.*[4] for the recovery kinetics of irradiated mammalian cells, and later developed by Elkind and Sinclair[5]. The model predicts that, concurrent with repair of sublethal damage, cells surviving the conditioning dose progress through the generation cycle into that portion of the cycle which is radiation sensitive and such cell progression gives rise to the minimum observed in most two-dose recovery curves.

Littbrand and Revesz[2] have reported that Ehrlich ascites tumour cells do not demonstrate recovery when irradiated in the anoxic state *in vitro*. It should be pointed out, however, that the challenge dose was delivered 18 h following the conditioning dose. No other time sequence was reported. Thus, little can be said concerning the early recovery kinetics of this cell line. In addition, cells were not kept anoxic between the fractions and this may have influenced the recovery response.

The differences in recovery kinetics demonstrated by 1-day and 6-day *P*-388 tumours irradiated *in vivo* may result from the fact that 6-day tumours consist of a population of cells which have been allowed to grow into the hypoxic state. This may give rise to a different tumour cell population age density distribution[6] which in turn would be expected to result in variation of the age response function[5]. Such differences in population composition and kinetics can give rise to variation in the recovery responses of such populations.

In summary, it has been demonstrated that malignant mammalian cells are capable of repairing sublethal radiation damage whether in the oxygenated or hypoxic state. The kinetics of the recovery response differ in that hypoxic tumour cells appear to repair sublethal damage at a slower rate than aerobic cells.

VETERINARY SCIENCE

'Ewe × Side' of Udder Interactions in Milk Yield in Relation to the Number of Lambs suckled

ONE method used to estimate milk yield of ewes at pasture during the course of experiments at Armidale, New South Wales, in 1960, was the oxytocin technique[1]. This involved injections of oxytocin to induce let-down, followed by an "emptying" milking and, 4 h later, a "measuring" milking, milk yield being calculated as a rate (g/h). The good agreement found between this technique and lamb suckling has already been discussed[2].

A ewe has only one major gland on each side, and production from the supernumerary glands is very small[3]. In this study milk production of the two halves of the udder was recorded separately, and supernumerary glands, when present, were included with the main gland. It has been shown by numerous authors[4–7] that ewes are not fully extended in milk yield when they are suckling singles. The milk yield of each gland can then be regarded as the result of an interaction between its potential to produce milk and the sucking stimulus of the lamb. A single lamb may equally stimulate each side of the udder, may consistently suck more on one side of the udder than the other or may change its preference from time to time. The stimulation of the two sides of the udder is likely to be more equal for twins than for singles because both sides will be more fully stimulated.

To investigate this point, analyses of variance (Table 1) on the milk yields of the two sides of the udder were

carried out for the first 10 weeks after parturition for six medium-wool Peppin and seven strong-wool Merino ewes suckling twins, and twelve Peppin and fourteen strong-wool ewes suckling singles. The main effects, ewes and weeks, and the 'ewes × weeks' interactions, which were very highly significant in all four analyses, are not shown. The 'ewes × sides' interactions are all highly significant, showing that, whether suckling twins or singles, some ewes produce more milk on the left and some more on the right. The variance components for these interactions, together with their 95 per cent confidence intervals, were calculated by Grayhill's method[8]. The 'ewe × sides' interaction component is significantly greater for singles than for twins for both strains (Table 2).

The significant 'ewe × sides' interaction, accompanied by a small and not significant 'weeks × sides' interaction, indicates an uneven stimulation of the sides which is consistent from week to week. If the ewe is fully stimulated by suckling twins, the unevenness can be interpreted as showing that the potential production for some ewes is greater on the left, and for others on the right. Because unevenness between sides is greater for single lambs than for twins it is likely that single lambs develop a consistent preference for the better side.

SOIL SCIENCE

Hydrolysis of Soil Nitrogen by Strong Acids

NUMEROUS tests have been proposed for determining the "available" nitrogen in soils, but although they have proved successful under some conditions, they have not generally been reliable for predicting field crop response[1–3]. Most of these methods are based on the estimation of nitrogen which can be readily hydrolysed by dilute acids[1] or mineralized by incubation over short periods of time[3]. It seems quite probable that nitrogen left in more resistant fractions of soil organic matter may also play a supporting part in supplying nitrogen that can be used by plants. Recent research at this Station indicates that more vigorous acid hydrolysis and extraction of soil releases considerable nitrogen from resistant organic complexes.

Soils from six plots at the Rhode Island Agricultural Experiment Station, which have a long history of treatment with various types of nitrogen fertilizer, were used in the investigation. The soil, classified as a Bridgehampton silt loam, has received continuous fertilizer, lime and cropping treatment for more than 60 years. Table 1 presents data on these soils pertinent to their nitrogen status and for later use in comparison with the acid hydrolysis investigations.

‡ Incubation at 30° C (ref. 3).

Hydrolysates were prepared by means of a modification of Bremner's procedure[4]. Soils were subjected to a series of sequential hydrolyses at 100° C using distilled water and 1, 3, and 6 N hydrochloric acid and sulphuric acid. A 4-in. round-bottom centrifuge tube containing 5 g of soil and 20 ml. extracting solution was placed in a boiling water bath. An 11-in. chromatographic tube containing a glass bead served as a condenser. After an hour, the tube was removed from the bath, allowed to cool and centrifuged. The hydrolysate was decanted and the residue washed with 10 ml. of fresh extractant by mixing well and centrifuging. The supernatant was decanted and combined with the previous hydrolysate. Twenty ml. of fresh solution was added to the residue and this mixture was again hydrolysed for a second hour. The same separation procedure was repeated. The residue was subjected to a similar hydrolysis for a final 2 h. This time the residue was washed with three 10-ml. portions of water. The residue was dried and saved for further analysis. The three acid hydrolysates (1 h, 2 h, and 4 h) were neutralized with sodium hydroxide (5 N and 0·5 N) to *p*H 6·5 ± 0·1 and made up to 100 ml. Ten-ml. portions of the extracts were used for all determinations.

Organic carbon was determined using a modification of the method devised by Tinsley[5]. Two grams of mercuric oxide were added to hydrolysates containing chloride ion to prevent reduction of dichromate[6]. Total nitrogen and alpha-amino nitrogen were determined by the micro-Kjeldahl procedures developed by Bremner[4].

It was found that there was little difference in the percentages of carbon and nitrogen released from the six soils. This was to be expected, as previous work had indicated the similarity of acid hydrolysable soil organic matter independent of the origin of organic residues[7,8]. However, there were large variations in relation to acid treatments (Table 2).

For carbon, an increase in the strength of either hydrochloric acid or sulphuric acid beyond 3 N did not materially increase the amount hydrolysed. A comparison with the water extraction indicates the degree of decarboxylation by acid hydrolysis. Nitrogen recoveries were directly related to increases in acid strength from 1 N to 6 N, resulting in a narrowing of the carbon/nitrogen ratios in the hydrolysates and a sharp rise in the ratios of the residues (Table 3). The wider carbon/nitrogen ratios of the first-hour hydrolysates suggest that easily dissolved materials (for example, carbohydrates) and some amino-acids and amino sugars were being extracted. The narrow ratios in the second hour are suggestive of more effective extraction of compounds containing greater

percentages of nitrogen. In general, the narrowest ratios occurred in the fourth hour. This could arise from the presence of resistant compounds in the hydrolysate.

The very wide carbon/nitrogen ratios of the residues might well indicate very resistant heterocyclic nitrogen compounds, such as humic substances. Felbeck[9] has proposed a possible structure for these compounds the carbon/nitrogen ratio of which (25/1) is similar to that found in several of the residues and particularly where hydrochloric acid is used. It has been shown by Stevenson[10] and Dubach and Mehta[11] that the optimum time for the liberation of hexosamines and amino-acids (non-humic substances) from soil, using 6 N hydrochloric acid, is 4 h. The data presented in Table 3 for alpha-amino nitrogen support these observations. It is suggested that a 4-h hydrolysis with 6 N hydrochloric acid extracts a large percentage of non-humic substances leaving behind in the residue essentially humic materials. The 6 N sulphuric acid solution is considerably less effective in its extraction of non-humic materials than 6 N hydrochloric acid. In all cases the carbon/nitrogen ratios of the hydrochloric acid residues are wider than those from sulphuric acid. This is because of the more effective extraction using hydrochloric acid and probably greater decarboxylation with sulphuric acid.

An appreciable fraction of the dissolved nitrogen in the hydrolysates was in the alpha-amino form (Table 4). The largest amounts were liberated in the first hour and decreased rapidly during the second- and fourth-hour periods. Amounts extracted were related directly to acid strength. At concentrations above 3 N, hydrochloric acid proved to be a much more effective extractant than sulphuric acid.

* Average of six soils
† Percentage of total nitrogen.

The average of 16·5 per cent extracted with 6 N hydrochloric acid is somewhat lower than others have reported[12,13]. However, the 4-h hydrolysis used in this investigation is considerably less than that used by others. Bremner[12] found that maximum liberation of amino-acids could be attained in about 12 h and that prolonged hydrolysis caused their destruction. It is believed that extending the time of hydrolysis would liberate a greater percentage of amino-acid, but it is doubtful that these values would be much higher than that obtained during the 4-h period. It is concluded that the soils contain rather limited quantities of alpha-amino nitrogen and essentially all this nitrogen is extracted in a few hours by acid hydrolysis.

Sulphuric acid	15·9	7 2	9 9

* Average of six soils.
† Percentage of nitrogen in hydrolysate.

Table 5 shows the amount of alpha-amino nitrogen dissolved based on the nitrogen released to the hydrolysate. With increasing acid strength the hydrochloric acid extracts from the second hour contain the largest amount of alpha-amino nitrogen. This supports the carbon/nitrogen ratio data of Table 3, which show a narrowing carbon/nitrogen relationship in the second hour attributed to the solubilization of nitrogen-rich compounds.

Although the data presented here do not relate nitrogen extracted by strong acid hydrolysis to crop response, it is suggested that such vigorous treatment and subsequent nitrogen measurement may be an approach to the estimation of nitrogen-supplying power of soils.

Microbial Factor in Short-term Phosphate Uptake Studies with Plant Roots

IN most investigations of the mechanisms of nutrient uptake by plant roots no attempt has been made to grow plants under sterile conditions. A prolific microflora develops on the root surface even in very young plants unless stringent precautions are taken to grow them

aseptically[1]. It could be envisaged that such a population may affect the results of nutrient uptake experiments either by influencing plant metabolism or by adding its own uptake to that of the root. Krasil'nikov[2] has shown that rhizosphere organisms can affect the amino-acid composition of barley.

Krasil'nikov[2] cites an instance in which phosphate uptake over 17 days was doubled by the presence of micro-organisms on barley roots, but the reverse occurred with woody plants. However, in neither instance was uptake examined in relation to root growth which can be affected by micro-organisms[3]. The reported lower total ash contents of non-sterile red clover and sunflower compared with sterile plants[4,5] were not examined in relation to root growth differences caused by the treatments. A recalculation of the data of Welte and Trolldenier[4] as total ash (mineral uptake) per g of root shows that non-sterile plants took up to 64 per cent more nutrients than sterile plants from nutrient culture solution over periods of approximately 30 days. Subba-Rao, Bidwell and Bailey[6] showed that in tomato plants, the roots of which were infested with *Fusarium* sp. or with *Trichoderma viride*, the tops contained less phosphorus-32, sulphur-35 and carbon-14 than sterile plant tops. This was after uptake periods of 48–72 h from nutrient solution containing radioactively labelled phosphate, sulphate and bicarbonate. However, total uptake was not studied and therefore the data refer only to translocation. As none of these authors have calculated the effects of micro-organisms on the efficiency of nutrient uptake, the present investigations were designed to investigate this using techniques commonly used by plant physiologists.

Tomato seeds (*Lycopersicon esculentum* var. 'Grosse Lisse') and subterranean clover seeds (*Trifolium subterraneum* var. 'Bacchus Marsh') were surface sterilized with 7 per cent calcium hypochlorite solution, washed with sterile water and germinated on a nutrient agar to detect contamination. Sterile germinated seeds were transferred to a stainless-steel mesh above 30 ml. of Hoagland and Arnon plant nutrient solution[7] in cotton-plugged test-tubes (3 × 20 cm) using three seeds per tube. Non-sterile treatments received 0·1 ml. of inoculum consisting of a 1 per cent suspension of Urrbrae loam (a red-brown earth) to provide a wide spectrum of micro-organisms. After 4–8 days' growth in a glasshouse, plants were tested for sterility and harvested before extensive branching of roots had occurred. The roots of the intact plants were washed in tap water for 60 sec to remove excess plant nutrient solution, placed in 5×10^{-4} M calcium sulphate for 2 h and then transferred to 5×10^{-4} M calcium sulphate containing 5×10^{-6} M potassium dihydrogen phosphate (*p*H 6·7) and phosphorus-32 as phosphate at 80 μc./l. (less than 10^{-8} M). After uptake periods ranging from 5–60 min the roots were washed in rapidly running water for 5 min and separated from the tops to estimate translocation. Twelve replicate plants were used for each treatment. Liquid scintillation counting was employed using a thixotropic base in which to suspend the plant material.

Root and top data for 5-day-old tomato and for 8-day-old subterranean clover (Table 1) showed little difference between sterile and non-sterile plants in these experiments. No differences in root hair production between sterile and non-sterile plants were detected. Differences in phosphate uptake (Table 2) between these sterile and non-sterile plants can therefore be ascribed directly to the micro-organisms and not to differences in plant morphology.

Table 1. ROOT AND TOP GROWTH OF STERILE AND NON-STERILE PLANTS*

Plant	Condition	Root length (cm)	Root dry weight (mg)	Shoot dry weight (mg)
Tomato	Sterile	7·7	0·24	2·7
	Non-sterile†	7·7	0·24	3·0

		Non-sterile	1,214§	1,138‡	59
	20	Sterile	1,225	971	119
		Non-sterile	1,906†	1,718‡	125

* Phosphate (10^{-12} moles) per plant. Means calculated from 12 plants after log transformation.
Differences between sterile and non-sterile: † Significant at 5 per cent level; ‡ significant at 1 per cent level; § significant at 0 1 per cent level.

Calculations made from the data in Table 2 show 77–95 per cent increases in uptake by non-sterile tomato and 55–60 per cent increases by non-sterile clover. The variation in uptake between replicate tomato and clover plants was great despite selection of apparently uniform plant material. In a 5-min uptake experiment with barley using twelve replicate plants, an 18 per cent increase in phosphate uptake was not significant at the 5 per cent level. Variation between non-sterile plants was greater than that between sterile plants.

In the absence of treatment/time interactions, uptakes over all time treatments were averaged in these experiments. Over the two time treatments for tomato, the increases in non-sterile plants in total uptake and root content of phosphorus-32 were significant at the 1 per cent level and the greater translocation in non-sterile plants was significant at the 0·1 per cent level. With clover data averaged over five time periods up to 60 min, the higher total uptake and root content of phosphorus-32 of non-sterile plants were significant at the 0·1 per cent level.

Uptake was greater in the non-sterile tomato by 85 per cent and non-sterile clover by 45 per cent over all time treatments, although there was virtually no difference in root and shoot growth between sterile and non-sterile plants. It is therefore suggested that phosphate uptake may be grossly overestimated by neglecting the need for complete asepsis in growing test material used in short-term uptake experiments. This type of experiment has often been used to postulate mechanisms of uptake and to estimate kinetic "constants" such as carrier concentrations[8–10]. The results refer especially to the use of low concentrations of phosphate; effects at higher concentrations and longer uptake times are under investigation.

Phosphate translocated to the top by tomato in 20 min was 4·4 times greater in non-sterile plants (this was significant at the 0·1 per cent level). A strong trend in the same direction occurred with clover after 60 min. The much higher phosphorus-32 content of tops of non-sterile tomato plants demonstrates conclusively that the increased phosphate uptake by non-sterile plants cannot be attributed solely to absorption by the rhizoplane microflora. A direct effect of micro-organisms on the metabolism of the plant is indicated.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned.

ASSISTANT LECTURERS (2) (with an honours degree in pharmacology, physiology, biochemistry or zoology) IN THE DEPARTMENT OF PHARMACOLOGY —The Clerk to the Council, The School of Pharmacy, University of London, Brunswick Square, London, W.C.1 (August 10).

RESEARCH ASSISTANT (with a good honours degree and preferably some research experience, but consideration will be given to applications from recent graduates) IN THE DEPARTMENT OF BIOLOGY, for work on the physiology of stomata—Prof. C. D. Piggott, Department of Biology, The University, St. Leonard's House, Lancaster, Lancs (August 10).

RESEARCH FELLOW (with a good honours degree in the social sciences and some research experience) IN SOCIOLOGY—The Registrar, The University, Sheffield (August 10).

LECTURER (with an honours degree in pharmacology, physiology or biochemistry and also a higher degree or with evidence of original research in an appropriate field) IN PHARMACOLOGY—The Clerk to the Council, School of Pharmacy (University of London), 29/39 Brunswick Square, London, W.C.1 (August 11).

SENIOR TECHNOLOGIST (male, with either a university degree in science or the A.I M.L.T. in bacteriology, and previous experience in microbiology) IN THE DEPARTMENT OF BACTERIOLOGY—Prof. F. S. Stewart, Department of Bacteriology, Trinity College (University of Dublin), Dublin 2, Republic of Ireland (August 12).

TEMPORARY DEMONSTRATOR OR TEMPORARY ASSISTANT LECTURER (with specialist experience in soil bacteriology) IN BOTANY—The Registrar, The University, Liverpool 3, quoting Ref. 170/N (August 13).

DEPUTY CHIEF REGIONAL PHYSICIST, PRINCIPAL PHYSICIST GRADE (with wide experience in medical physics) IN THE REGIONAL MEDICAL PHYSICS DEPARTMENT—The Secretary, Sheffield Regional Hospital Board, Fulwood House, Old Fulwood Road, Sheffield, 10, quoting Ref. N3266/2 (August 15).

JUNIOR/SENIOR RESEARCH ASSOCIATE (graduate in psychology with strong research interests) IN THE DEPARTMENT OF PSYCHOLOGY to work under the supervision of Dr Gerald H. Fisher on a research project concerned with fundamental aspects of perception—The Registrar, The University, Newcastle upon Tyne, 2 (August 15).

RESEARCH STUDENT IN ASTRONOMY in St. Salvator's College to undertake research in observational or theoretical astronomy at the University Observatory under the direction of Prof. D. W. N. Stibbs—The Secretary, University of St. Andrews, College Gate, St. Andrews, Fife (August 15).

SENIOR LECTURER (medically qualified) IN THE DEPARTMENT OF BACTERIOLOGY—The Registrar, The University, Liverpool, 3, quoting Ref. OV/169 (August 19).

SENIOR SCIENTIFIC OFFICER/SCIENTIFIC OFFICER (preferably ex-Service candidate, with an honours degree in agriculture, science or food science, preferably with postgraduate experience in bacteriology) IN THE AGRICULTURAL BACTERIOLOGY DIVISION of the Ministry of Agriculture, to undertake research and investigational work in connexion mainly with the bacteriology of meat and meat products, and possibly to undertake some teaching duties in the Faculty of Agriculture, Queen's University, Belfast—The Secretary, Civil Service Commission, Stormont, Belfast 4, Northern Ireland (August 19).

ASSISTANT LECTURER OR LECTURER (with an honours degree in biochemistry, agricultural biochemistry, or some equivalent qualification) IN THE DIVISION OF AGRICULTURAL BIOCHEMISTRY, School of Agriculture, University of Aberdeen and North of Scotland College of Agriculture—The Secretary, The University, Aberdeen (August 20).

ASSISTANT LECTURER (with special qualifications in Greek philosophy) IN PHILOSOPHY—The Registrar (Room 39, O.R.B.), The University, Reading (August 20).

LECTURER OR SENIOR LECTURER IN HISTOLOGY OF NEURO-ANATOMY IN THE DEPARTMENT OF ANATOMY—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (August 20).

RESEARCH ASSISTANTS (with an appropriate honours degree of a British university or exceptionally an equivalent qualification) IN MECHANICAL ENGINEERING; ELECTRICAL ENGINEERING; CIVIL ENGINEERING; POLYMER CHEMISTRY (two posts); PHYSICAL ORGANIC CHEMISTRY; PHYSICAL METALLURGY; MATHEMATICS; PHYSICS; BIOLOGY (Plant Physiology); and a RESEARCH ASSOCIATE IN ELECTRICAL ENGINEERING—The Principal, Lanchester College of Technology, Priory Street, Coventry (August 22).

TEMPORARY ASSISTANT LECTURER (preferably with a special interest in political and moral philosophy) IN PHILOSOPHY—The Registrar, The University, Manchester 13, quoting Ref. 180/66 (August 24).

CHAIR OF PRODUCTION ENGINEERING IN THE DEPARTMENT OF PRODUCTION AND INDUSTRIAL ADMINISTRATION—The Registrar, The College of Aeronautics, Cranfield, Bedford (August 26).

ASSISTANT EDITOR (with experience of research and publication in medical or veterinary entomology, good critical faculty and ability to write lucid and concise English, and preferably a reading knowledge of other European languages) at the Commonwealth Institute of Entomology, London, S.W.7, for duties which will include producing and editing the Institute's publications—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Slough, Bucks (August 31)

ASSISTANT LECTURER -IN AERONAUTICAL ENGINEERING—Prof. A. V. Stephens, The Queen's University, Belfast, Northern Ireland (August 31).

CURATOR VETERINARIAN (registered veterinary surgeon) to be in charge of the Small Animal Breeding Station—The Secretary, University of Edinburgh, Old College, South Bridge, Edinburgh (August 31).

LECTURER/SENIOR LECTURER (preferably with research activities in one of the following fields: ionization, discharge and plasma physics, solid state physics and ionospheric physics) IN PHYSICS at the University of New England, Armidale, New South Wales, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, August 31).

POSTDOCTORAL RESEARCH FELLOW IN BIOCHEMISTRY/IMMUNOLOGY for work in connexion with a project under the joint direction of Dr. I. G. Murrey and Dr. W. D. Brighton concerning the extraction and characterization of the antigens of organisms involved in farmer's lung—The Personnel Officer, Central Public Health Laboratory, Colindale, London, N.W.9 (August 31).

RESEARCH OFFICER IN THE DEPARTMENT OF PHYSICS to investigate damage occurring in high-power laser systems—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 31).

SENIOR DEMONSTRATOR IN THE DEPARTMENT OF INORGANIC CHEMISTRY —The Registrar (Appointment E.55), The University of Melbourne, Parkville, N.2, Victoria, Australia (August 31).

DEPARTMENTAL GRADUATE ASSISTANT IN THE DEPARTMENT OF MICROBIOLOGY to assist in the preparatory work for practical classes and demonstrations—The Registrar, The University, Newcastle upon Tyne, 2 (September 1).

SENIOR LECTURER OR LECTURER IN BOTANY (Plant Physiology) at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (September 2).

SENIOR LECTURER and a LECTURER or ASSISTANT LECTURER IN GEOLOGY at the University of Ife, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 3).

LECTURER IN EXPERIMENTAL ZOOLOGY—The Secretary, The Queen's University, Belfast, Northern Ireland (September 7).

HOLBROOK GASKELL CHAIR OF BOTANY—The Registrar, The University, Liverpool (September 10).

LECTURER or SENIOR LECTURER (with special interests in physical chemistry) IN THE DEPARTMENT OF CHEMISTRY, University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 16).

LECTURER (qualified in one or more of the following fields: biometry, agricultural statistics, biomathematics, mathematical statistics, an agricultural or biological discipline with supplementary experience in its mathematical or statistical aspects) IN BIOMETRY IN THE DEPARTMENT OF AGRICULTURAL BOTANY, University of Sydney, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 16).

READER or SENIOR LECTURER IN GEOGRAPHY at the Australian National University—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 16).

HARRISON CHAIR OF MECHANICAL ENGINEERING—The Registrar, The University, Liverpool (September 17).

SECOND CHAIR OF CIVIL AND STRUCTURAL ENGINEERING—The Registrar, The University, Sheffield (September 17).

SENIOR LECTURER/LECTURER IN GEOGRAPHY at Rhodes University, Grahamstown, South Africa—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (South Africa and London, September 18).

DIRECTOR (with a veterinary qualification, high scientific attainment in a relevant science, and preferably some experience of administration) OF THE INSTITUTE FOR RESEARCH ON ANIMAL DISEASES, Compton, Newbury, Berkshire—The Secretary, Agricultural Research Council, Cunard Building, 15 Regent Street, London, S.W.1 (September 19).

LECTURER/ASSISTANT LECTURER/SENIOR DEMONSTRATOR (with special qualifications and interests in the field of biogeography) IN THE DEPARTMENT OF GEOGRAPHY, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, September 30).

PLANT NEMATOLOGIST with a good degree in the biological sciences, experience in the identification of the nematode parasites of economically important crops, and an interest in taxonomy) IN THE COMMONWEALTH BUREAU OF HELMINTHOLOGY, St. Albans—The Secretary, Commonwealth Agricultural Bureaux, Farnham House, Farnham Royal, Bucks (September 30).

SENIOR LECTURER (with an honours degree in electrical engineering (or mechanical and electrical engineering) with industrial and/or research experience in power system analysis or electrical machines (specification of design) preferred) IN THE DEPARTMENT OF ELECTRICAL ENGINEERING, University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 1).

LECTURER (with a degree in pure science or agricultural science) IN PLANT PATHOLOGY at Lincoln College (University of Canterbury), New Zealand—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, October 31).

CHEMISTS (with a good honours B.Sc. degree, and preferably of Ph.D. standing) to work in fields such as relation between structure and properties in polymeric materials, modification of polymer properties by cross-linking and grafting, the application of reverse osmosis to the desalination of water and to non-aqueous systems, applications of physico-chemical methods, such as light scattering, to determine molecular weights and biomedical applications of new membranes—The Director, Arthur D. Little Research Institute, Inveresk, Musselburgh, Midlothian.

HEAD OF THE DEPARTMENT OF MATHEMATICS AND PHYSICS; and HEAD OF THE DEPARTMENT OF MECHANICAL ENGINEERING—The Secretary, Wolverhampton College of Technology, Wolverhampton.

HISTOPATHOLOGIST (with a medical or veterinary degree, postgraduate experience in histo-pathology, and preferably general research and/or specialized knowledge of histo-chemistry) IN THE DEPARTMENT OF EXPERIMENTAL PATHOLOGY, Chester Beatty Research Institute, Fulham Road, S.W.3 —The Secretary, Institute of Cancer Research, Royal Cancer Hospital, 34 Sumner Place, London, S.W.7, quoting Ref. 300/G/25.

INSECT PATHOLOGIST (microbiologist, preferably with experience in bacteriology, mycology, virology, or protozoology) to study insect diseases and their possible utilization in pest control—Division of Entomology, University of California, Berkeley, California 94720, U.S.A.

INSTRUMENT TECHNICIAN (with technical college training, some years of experience in instrumental techniques related to chemistry, and fully conversant with the operation of UV and IR equipment) IN THE DEPARTMENT OF CHEMISTRY to undertake routine NMR mass spectrometric, IR and UV spectrophotometric analyses and to interpret simple spectra (training will be given in NMR and mass spectrometry)—Prof. A. Bourns, Chairman, Department of Chemistry, McMaster University, Hamilton, Ontario, Canada.

LECTURER or RESEARCH ASSOCIATE (with qualifications and/or experience in the fields of metallurgy or ceramics) IN THE DEPARTMENT OF PHYSICS— The Registrar, University of Bristol, Senate House, Bristol, 2.

MICROBIOLOGIST (Ph.D. or equivalent) to supervise clinical microbiology and the Diagnostic Chemical Laboratory servicing 285 beds—The Assoc. Director of Research, National Jewish Hospital, 3800 E. Colfax, Denver, Colorado 80206, U.S.A.

ORGANIC CHEMIST (Postdoctoral) for structure elucidation studies on the phenolic constituents responsible for the pigmentation of wheat bran—Prof. D. J. Baisted, Science Research Institute, Oregon State University, Corvallis, Oregon 97331, U.S.A.

PHYSIOLOGIST/BIO-PHYSICIST to study physiological response to controlled changes in environmental conditions—D. C. Page, Head of Personnel Services, The Electricity Council, Research Centre, Capenhurst, Chester, quoting Ref. N/28.

RESEARCH ASSISTANT (preferably with postgraduate biochemical experience) for investigations on calcium metabolism—Dr. M. R. Wills, Department of Chemical Pathology, Royal Free Hospital, Gray's Inn Road, London, W.C.1.

RESEARCH FELLOW IN CHEMISTRY for work which will include the synthesis and the determination of physical properties of heterocyclic boron compounds —The Secretary, Royal Holloway College (University of London), Englefield Green, Surrey.

RESEARCH HISTOPATHOLOGIST in the Paterson Laboratories, with responsibility for the supervision of work on small animal pathology—The Director of Research, Paterson Laboratories, Christie Hospital and Holt Radium Institute, Manchester, 20, quoting Ref. 5059.

RESEARCH STUDENTS (honours graduates or others having equivalent qualifications in engineering, physics or mathematics) IN THE DEPARTMENT OF ELECTRONIC AND ELECTRICAL ENGINEERING, to join a group concerned with theoretical, computational and experimental aspects of the formation and noise properties of high-perveance electron beams—The Registrar, The University, Sheffield, 10.

SCIENCE GRADUATE (preferably biochemist or chemist) to work on cholinesterase isoenzymes—Dr. M. Whittaker, Department of Biochemistry, University of London, King's College, Strand, London, W.C.2.

YOUNG POSTGRADUATE PHYSICISTS, MATERIALS SCIENTISTS, ELECTRICAL ENGINEERS, and MECHANICAL ENGINEERS to work on a new approach to the use of conducting, dielectric, and magnetic materials (also materials with compound properties) in such applications as cabling, wiring, switching (at distribution, industrial and domestic voltages), heat transfer, and electrical machines—D. C. Page, Head of Personnel Services, The Electricity Council Research Centre, Capenhurst, Nr. Chester, quoting Ref. N/35.

RESEARCH COMPUTERS

THE Computer Board now established by the Secretary of State for Education and Science is an important innovation in the administration of academic research, at least in Britain. Though the questions which are being raised about the adequacy of the plans for providing universities with computers are real enough they are in some ways less important than the issues of principle created by the existence of the Computer Board. For one thing, it is an organization that cuts across the autonomous instincts of British universities. Still more remarkably, its decisions will cut across the boundaries between universities and that important sector of the scientific research which is at present undertaken directly by the research councils. Finally, its work in the next few years is certain to determine a pattern for the use of computers in scientific research for decades to come. In other words, it is a powerful body, and is almost certain to be influential as well.

The first thing to be said is that the complaints now being made about the immediate plans for installing computers are in one sense inevitable and in another irrelevant. The Working Group under Prof. Flowers (see p. 675 of this issue) was always clear that its five year plan would have to be re-modelled every year, and this point has apparently been accepted by the Government. Indeed, the chief task of the Computer Board is to bring the planning up to date. The first thing to be done, now that the core of the membership of the board has been appointed, is to see whether the experience of the past few months is enough to justify a massive expenditure on multiple access computing machinery. Even though it would be a surprise to many people if that brave new world were already here, there is nothing in the constitution of the Computer Board to prevent it saying that the plans of a year ago are now old hat, and must be discarded.

The fact that the work of the Board will cut across the autonomy of the universities is not as fearsome as it sounds. There are sound precedents for a collective decision by the universities that important items of equipment should be acquired and managed collectively. The National Institute for Research in Nuclear Science, with its co-operative accelerators, is the most obvious example. But the decisions of the Computer Board may have wider implications. Some universities may, for example, be told that neighbouring institutions must have access as of right to their computer installations. Others will find themselves being persuaded not to acquire the computer they would prefer to have but some other that will more easily fit into a national network. Although at first sight decisions like this seem to bristle with difficulties, universities as a whole are well aware that they will be better off with a balanced network of computers spread through the country than with an extension of the present system of individual acquisition and management. That, at least, is the present mood. One of the tasks of the Computer Board will be to persuade the universities and the research establishments that future instalments of the computer plan are as sensible as was the Flowers Report a year ago.

The relationship between the Computer Board and the research councils is also important. Though the Computer Board may seem to the universities to be a kind of University Grants Committee with special responsibility for computers, to the public laboratories maintained by the research councils it will be an entirely novel creature. This is one of the ways in which its work may be most rewarding, for the gulf between the universities and the public research laboratories has traditionally been too wide. All kinds of facilities which might be shared are kept too much in isolation. The movement of people between the two kinds of institutions is similarly less fruitful than it might be. So it is tempting to hope that if the Computer Board can establish close liaison over the admitted immediate need of a better computing system, the parties to that shot-gun marriage will recognize that their common interest is really very much more extensive.

It is also to be hoped that the good sense of these arrangements will soon be even more widely appreciated. Although the Computer Board is to help in formulating the forward planning of the public laboratories working under the research councils—the research councils for science, agriculture, medicine, the natural environment and, no doubt in time, social science—the public laboratories now under the wing of the Ministry of Technology will remain apart. One of the more obvious awkwardnesses of this arrangement is that institutions such as the Royal Radar Research Establishment, the Royal Aircraft Establishment and the National Physical Laboratory are at once among the largest and most experienced of British users of computers, and similar to the universities in the character of their need. Fortunately the links between the Atomic Energy Authority—another dependant of the Ministry of Technology—and the universities on computing machinery are close enough, and there is no reason why other establishments should not seek to develop in a similar way. In the long run some formal integration of the two parallel systems will be essential.

Another defect in the present arrangement is that there is no means of restraining the demand of the universities for extra computing power. At this stage, of course, such a restraint would be unwise. British universities and research laboratories are not as well provided for as they should be, and there is probably a need that the Computer Board, like the Flowers Group before it, should do something to force

the pace. But it will not indefinitely be possible to meet an unrestrained demand. Sooner or later it will be necessary for those who use computers to work out more explicit arrangements for making the most economical use of them. One difficulty is that the diversity of the demand on computer power will make it harder to operate the kind of committee system which has proved successful in managing the big accelerating machines. In any case, it is hard to see how a committee would ever be able to decide confidently between the merits of some complicated analysis in demography and a Monte Carlo calculation in nuclear physics.

The question remains of how the Computer Board may serve as a model for the development of sectors of research in British universities. The first need, of course, is that the board should show that it can function effectively. The special characteristics of computers, and the obvious need of integration within the system, also restrict the usefulness of comparison with other fields of research in which development is necessary. It is nevertheless tempting to wonder whether it will not turn out that the need for development in, say, molecular biology can best be met by independent board given the means and the responsibility for seeing that developments at universities and research establishments are sensibly co-ordinated blessed with funds. Evidently the Computer is more important than the narrowness of its of interest would suggest.

WE WUZ ROBBED

THE World Cup which has recently been enacted in Britain may have been fun to watch, but there is no question that it was a thoroughly badly designed experiment. If the intention was to find out which football team is the best in the world, the organizers would have gone about their task quite differently.

Just as the frequency of deaths from kicks by horses in those far-off but now classical stables of the Prussian Army are described by a Poisson distribution, so are the numbers of goals scored by the competing teams in the recent series of World Cup matches. Table 1 shows the numbers of occasions during the series of thirty-two games (each involving two teams) on which specified numbers of goals were scored, together with the frequencies described by a Poisson distribution of the form $P(n) = e^{-q}q^n/n!$ with $q = 1{\cdot}234$, or the mean of the observed scores.

Table 1

Numbers of goals	Observed	Calculated $65.P(n)$
0	18	18·4
1	20	22·8
2	15	14·0
3	7	6·0
4	2	1·8
5	2	0·5
More than 5	0	0·7

In reality an even better agreement between fact and prediction can be obtained by taking $q = 1{\cdot}27$, a value which lies well within the standard deviation of the mean.

The mere fact that a Poisson distribution can describe so well the distribution of scores by individual teams goes a long way to suggest that the teams were much of a muchness in talent and their scores were independent of each other. From this point of view, the decision that the outcome of the whole competition should depend on the outcome of a single game between the two so-called finalists was as much of a farce as a great many West German supporters already know it to have been. If it is assumed that the goal scoring potentiality of the two teams is equally well described by the Poisson distribution already specified, the chance that the result will be a draw is a mere 0·27. In other words, if two teams are equally matched, the chance that the result will be an active injustice to one of them will be 0·73. By the same token, a team which is slightly less skilled than its opponent can nevertheless expect a one in three chance of winning the deciding match.

Chancy outcomes of individual games are given extraordinary importance by the overall design of the World Cup competition, in which small groups of team play an incestuous competition on their own before one team is sent on to another stage in the competition. Obviously a properly randomized block design would be an improvement. But even within the framework of the existing competition, much could be done to reduce the gross sampling error under the present arrangements. Replication of the crucial games by a series of identical trials is one obvious remedy, and the organizers of the World Series of baseball games in the United States have in this spirit arranged that the winner should be the one who wins the most of seven games. The ideal is that in future World Cup competitions, the organizers should fix a certain limit of confidence (say, $P < 0{\cdot}01$) and then that they should require that the finalists go on playing against each other either until the superiority of one or the other of them is properly established, or until both parties agree to negotiate a draw.

A more practicable alternative might be to redesign the parameters of the game of football in such a way that a respectable degree of confidence in the outcome of the competition can be acquired in a reasonable interval of time. If, for example, it were agreed that single cup finals should remain, but that no team should be declared the winner until its score exceeds that of its opponent by three standard deviations of Poisson distribution, it might be necessary to design the game of football so that it would be practicable for one side to score 100 goals or so within the limits of endurance of the spectators. This implies that the parameter q would have to be much greater than under the present rules. Such a change could easily be brought about, possibly by widening the goals or by abolishing goalkeepers. The precise method by which these matters are attended to is, of course, much less important than that they should be dealt with quickly. The whole of South America knows that.

NEWS AND VIEWS

COMSAT's High Hopes

COMSAT, the United States Communications Satellite Corporation, may be pushing its luck too far. In four years, it has done better than anyone could have expected when Congress patched it together in a series of compromises between the advocates of public and private ownership. (Half of COMSAT's shares are owned by public shareholders, the other half by the American communications industry.) Even COMSAT's purpose was two-headed—the corporation was told to set up a global network of communications by satellite as soon as possible, and at the same time to enlist international partners willing to join in a system dominated by Americans.

Yet all this has been done. And quickly too. At home the corporation is a constant favourite with small investors, to the surprise of experts in Wall Street, yet it keeps cordial relations with the American Telephone and Telegraph Company, its biggest corporate shareholder. Abroad, it has set up the International Telecommunications Consortium which fifty-two countries have joined: the Philippines and Indonesia are recent recruits, and Yugoslavia is thinking about it—the first communist country to do so. (The consortium, INTELSAT, is the actual owner of the *Early Bird* satellite; COMSAT is the manager.) *Early Bird*, while by no means working to full capacity, has been successful enough for the transatlantic rates to be reduced. By the end of this year, COMSAT will be able to offer satellite communication over most of the world, as it launches a bigger version of *Early Bird*, capable of reaching ground stations in South America, and a satellite for the National Space and Aeronautics Administration which will provide circuits to the Far East. And by 1968, it will have put into orbit four advanced synchronous satellites for INTELSAT, making a full global network a reality.

But COMSAT is not content to have built so much on the ambiguities of the Communications Satellite Act of 1962. It is now arguing righteously to the Federal Communications Commission (FCC) that Congress gave it a mandate to have a monopoly over satellite communication at home as well as abroad. There is a rich prize at stake: the right to provide communication by satellites between the east and west coasts of the United States, and the country's far-flung hinterlands as well. The issue was raised when the American Broadcasting Company, one of the United States three major television networks, asked the FCC for permission to put up its own satellite, so that it could relay its own programmes. (The three networks now pay the American Telephone and Telegraph Company about $65 million a year from transmitting their shows around the country.) Most likely the FCC would not like to rule in favour of the crowded sky with every newspaper, television network and wire services allowed to have its own satellite. But COMSAT's claim that Congress had domestic satellites in mind in 1962 is laughable.

This has been politely pointed out by the Ford Foundation, in a brilliant brief prepared for the FCC which says, in effect, that COMSAT has had enough favours from the Federal Government to satisfy any corporation and that it should stick to its international business. What the foundation wants is an American satellite system to be run by a private—non-profit, non-governmental—corporation. That would relay *Batman*, *Peyton Place* and other staples for the commercial networks at a cheaper rate than they now pay; with its revenues, the corporation could provide, on five channels in each time zone, a mixture of public affairs and education.

There is no sign that the FCC will be tempted by such an adventure. The pressure from COMSAT is strong; it wants to be as powerful as possible by 1969 when the international agreement which the consortium's members have signed comes up for permanent ratification, so that its partners will not be tempted to join any rival system, and that hold-outs, notably the Soviet Union, will be tempted in. The FCC is in an unenviable spot—it must do what Congress could not do four years ago: make decisions about the future of a technology which is only just coming into existence. Along with its utopian plan, the Ford Foundation gave the FCC some wise advice: do not grant any hasty monopoly before the Carnegie Corporation's enquiry into the future of non-commercial television in the United States comes out. COMSAT could use the time to think whether the international perspective that it will need in 1969 to attract communist partners into a permanent relationship will be helped by its alliance with American commercial television.

Industrial Training

THE first clutch of the reports from the industrial training boards is an unsurprising demonstration that a lot will have to be done before the Industrial Training Act of 1964 brings all the benefits that its sponsors were hoping for. In particular, it is plain that the boards have not yet moved far into the field where most is expected of them—the training of adults, as distinct from juvenile workers, in the techniques of modern industry. Indeed, the three reports which are available, for the engineering, iron and steel and shipbuilding industries (*H.C.* 122, 123 and 124 respectively, H.M.S.O., 1*s.* 9*d.*), show that the past year has been something of a rush for all of them, with the occupying of new premises and the recruitment of staff dominating everything. (The board for the engineering industry has also been able to run up an overdraft of close on half a million pounds.)

The fourteen boards so far established have a right to collect a levy from all except the smallest industrial companies, and a duty to return some of what they collect to those companies with adequate training schemes. The funds thus available will enable the boards to arrange for training facilities for employees not otherwise catered for, either on premises of its own or elsewhere. It is also intended that each of the boards should recruit and train officers who will, in turn, help companies with their training plans. This is where the three boards whose reports have so far appeared seem to have done most in the past twelve months.

This, however, is only a beginning. The scale on which they will be operating in the future can be told from the estimate of the engineering training board—

admittedly the largest—that its annual levy, at a rate of 2·5 per cent of industrial turnover, will amount to £75 million—a sum not very different from the £130 million spent on British universities in a year.

In the administration of this levy and the compensating grants to companies, the boards must necessarily act as judges of what is good practice. But how do they know what is good? The engineering board has taken a step in the right direction by advertising its willingness to make grants for "research projects directed towards improving the effectiveness of training". It will be interesting to see how soon such work can provide an objective evaluation of the benefits (or otherwise) of the industrial training, which has necessarily grown up in a somewhat empirical fashion.

Ornithology in 1966

DR. D. W. SNOW, of the British Trust for Ornithology, writes: "The fourteenth International Ornithological Congress, which took place at Oxford during July 24–30, was the largest ever held, with some 900 members from forty-four countries. The 130 papers presented were ample proof that research in birds continues to make important advances in such diverse fields as systematics, behaviour, reproductive physiology and population dynamics. This has indeed been so for the last 25 years, as shown by such books as Mayr's *Systematics and the Origin of Species*, Tinbergen's *Study of Instinct*, and Lack's *Natural Regulation of Animal Numbers*, which draw more of their examples from birds than from any other group of animals. But the Congress also reflected some newer trends in ornithological research.

"Most strikingly, ethology, in the restricted sense of the study of the causal analysis or motivation of behaviour, was not represented at all. Instead, most of the papers on behaviour dealt with the development and function of song and other vocalizations, a field in which rapid advances have been made in recent years thanks to the sound spectrograph. One paper in particular, by Prof. Niko Tinbergen, Secretary General of the Congress, stressed the adaptive significance of specific behaviour patterns in the context of the whole ecology of the species, an aspect of behaviour which has been rather neglected.

"Evolutionary studies also showed a change of emphasis. Studies of geographical variation and speciation were rather few; in birds this is well-worn ground and the main established principles are not likely to alter. Instead, there were several papers dealing with evolution at the family level or higher, among them an account of Prof. Charles Sibley's studies of avian haemoglobins and egg-white proteins These studies are likely to clear up many of the debated problems of the relationships between the various orders of birds, for which the evidence from morphology is equivocal.

"The paper by the President of the Congress, Dr. David Lack, opened the eyes of many ornithologists to the wider significance of aspects of bird behaviour and ecology which have often been studied in isolation from each other. Entitled "Inter-relationships in Breeding Adaptations", it aimed to show that the type of nesting dispersion (colonial or widely spaced, for example), the nature of the nest site, the incubation and fledging periods, the type of young (whether nidicolous or nidifugous), the ability of the parent birds to defend their nest, and food and feeding habits are all inter-connected. None of them can be fully understood without reference to the others. Dr. Lack drew his examples from sea birds because they have been the subject of many detailed studies in recent years, but the same principles probably apply to all. (Prof. Tinbergen's paper, already mentioned, was planned jointly with Dr. Lack's and dealt with essentially the same theme from the point of view of behaviour.) This approach is likely to prove fruitful, and will make evolutionary sense of many facts which now seem merely isolated details.

"Several contributions at the Congress dealt with new techniques of radio-telemetry which will in coming years undoubtedly lead to great advances in the study of populations and migration and orientation. It is already possible to record for each of fifty-two birds simultaneously one location every 45 sec, and to plot the results automatically on maps. The possibilities are boundless, and more will undoubtedly be heard of them at the next Congress four years hence"

More River Meandering

A FURTHER development in the theory of river meandering has now appeared as *Professional Paper* 422-*H* of the United States Geological Survey. The paper is credited to Dr. Luna Leopold and Mr. W. B. Langbein, respectively the chief hydrologist and a research hydrologist with the U.S. Geological Survey, both of whom have been closely associated with the theory of river meandering for the past decade, particularly since Dr. H. von Schelling showed, in 1951, that the meandering of rivers is really a random walk problem[1,2]. By field studies of actual rivers, it has now been shown that there is a negative correlation between the meandering of rivers and certain other characteristics of the bed of a river which dissipate energy. Briefly, the studies have confirmed what successful fishermen have known for centuries—the more sinuous a river, the smoother the bed and the more uniform the velocity of flow.

The starting point for Von Schelling's theory is the hypothesis that the probability of a river deviating by an angle $d\phi$ from its previous direction in a distance ds is best represented by a Gaussian distribution. This leads to the conclusion that the shapes of rivers should be determined by the condition that:

$$\Sigma(\Delta\phi)^2/\Delta s$$

should be a minimum. With suitable approximations, this boils down to the assertion that the shape of a meandering river can be obtained from an equation:

$$\phi = \omega \sin 2\pi(s/M)$$

which specifies the deviation of the river (ϕ) from the direct path at all distances s along the loop the total length of which is M. The constant ω is a measure of sinuosity. Observation in the past decade has shown that a great many meandering rivers can be adequately accounted for by such a formula.

What Leopold and Langbein have now done is to obtain a correlation between the sinuosity of a river and the variances of depth, velocity, slope and shear, and also with a parameter which is a measure of frictional forces at the bed of the river. They have

worked in detail with five stretches of water in Wyoming, using techniques of recording the level of the water surface to within 0·001 in. on some occasions. They have found that when a reach of river is virtually straight, the variance of the chosen parameters of shear and friction near the bed tends to be much higher than when nearby reaches on the same river are sinuous. These and other correlations tend to confirm what the authors have been suggesting for some time—that the rate of dissipation of energy along the length of a meandering river tends to be a constant.

Fisheries Research at Aberdeen

DR. P. T. GRANT writes:

"The new laboratory of the Natural Environment Research Council's Fisheries Biochemical Research Unit was formally opened on April 27 by Sir Rudolph Peters at a ceremony presided over by Dr. E. M. Wright, Principal and Vice-Chancellor of the University of Aberdeen, in the presence of Mr. R. J. H. Beverton, Secretary of the Natural Environment Research Council.

"Completed in November 1965, the new laboratory is located in the Torry district of Aberdeen, overlooking the sea and the estuary of the River Dee. It is adjacent to the Marine Laboratory of the Department of Agriculture and Fisheries for Scotland and to the Torry Research Station of the Ministry of Technology. The building is on two floors with a total area of 10,000 sq. ft. The main and upper floor contains the laboratories, library, cold room and offices. The flexible system of laboratory furniture was designed and manufactured locally. All service rooms are on the ground floor, which includes an animal house for small mammals and an aquarium. A sea-water reservoir of 10,000 gallons capacity serves to maintain marine organisms at controlled temperatures in glass-fibre or plastic tanks. The architects were Mackie, Ramsay and Taylor of Aberdeen and the main contractors, Alexander Hall and Son, Ltd.

"The running of this research laboratory is an interesting venture in co-operation between the University of Aberdeen and the Natural Environment Research Council in that the University employs the staff and administers the unit, with funds provided by the research council. Both bodies are equally represented on the joint management committee and the unit has close links with the Department of Biological Chemistry. As director of the Unit and a reader in the Department of Biological Chemistry, I find that this close association has greatly helped members of staff to take part in teaching activities of the appropriate university departments although, of course, their primary obligation is to research.

"The research programme is concerned with the basic biochemistry of marine and freshwater organisms and the laboratory is equipped to carry out a broad range of metabolic studies. Problems under investigation by the present research staff of five and two research students include studies on the function and biosynthesis of biologically active molecules such as enzymes and hormones. A study of the variants of enzymes present in the tissues of marine organisms should have a bearing on the genetics of fish."

Parliament in Britain

IN the House of Commons on August 3, Mr. H. Jenkins was given leave under the Ten Minute Rule to introduce a Bill which would enable the Postmaster General to establish a Television and Radio Authority, to run the fourth television channel, and to set up a National Popular Radio Programme which would act as a parent station to local radio stations. Moreover, the Bill would enable the Postmaster General to abolish pirate radio stations within or without territorial waters. The new public authority would acquire its main revenue from advertising and its first task would be to replace the pirates in a manner acceptable to their audience and to the writers' and performers' unions and organizations. Mr. Jenkins mentioned that Radio 390, for example, was interfering with Swedish radio broadcasts and with shipping broadcasts on the Medway. The Authority would also support the University of the Air.

IN a statement in the House of Commons on August 3, the Postmaster General, Mr. E. Short, said that the Post Office now faced considerable problems of expansion, modernization and reorganization. In considering the present appropriateness of the Civil Service context in which the Post Office functions, the Government had recently made a fundamental survey of its management, structure and functions. After careful consideration it had been decided that instead of being a Department of State with a Minister at its head, the Post Office should become a public corporation and its members would be appointed by and responsible to a Minister. A final decision on the exact form of the reorganization and of the structure of the internal management must await the report of the Select Committee on Nationalized Industries, which was now examining the Post Office, and the fullest consultation with representatives of the staff which would now take place. A White Paper setting out the Government's final proposals would be presented to the House in due course. Employees would cease to be civil servants, and as regards management he hoped there would be cross-fertilization with industry. The present system of regulations would not obtain, but whether or not the Savings Bank was managed by the new corporation, banking policy would remain in the hands of the Treasury. It was intended to separate the postal and telecommunications services as completely as possible.

IN a statement to the House of Commons on August 4, the Prime Minister, Mr. H. Wilson, announced that it was the Government's firm intention to find time to pass the Parliamentary Commissioner Bill through all its stages in both houses by the end of the year. The Bill was given its first reading on July 20. Meanwhile it had been decided that, without prejudice to full discussion of the Bill itself, it would be prudent to designate the first Parliamentary Commissioner, who would be an Officer of the House of Commons, with a high degree of independence, dealing with complaints transmitted to him by members and reporting back to them individually, to the House as a whole and to whatever Select Committee the House might appoint. Mr. Wilson's announcement of the choice of Sir Edmund Compton was warmly welcomed by the Leader of the Opposition, though the appointment was criticized by Mr. J. Grimond as an encroachment on parliamentary freedom.

University News:

Indiana

PROF. H. GEST, at present professor of microbiology in Washington University, Missouri, has been appointed professor of microbiology and chairman of the Department of Microbiology in Indiana University.

Washington

DR. J. L. DEC. DOWNER has been appointed professor of ophthalmology in the University of Washington Medical School, Seattle, and is therefore resigning his position as director of the Medical Research Council's Cerebral Functions Research Group. It is expected that the activities of the Group will continue under a new director. Over the past few years the work of the Group has been concerned with learning and memory functions in monkeys utilizing the "split-brain" technique.

Appointments

MR. DUDLEY SEERS, director-general of Economic Planning at the Ministry of Overseas Development, will be the first director of the Institute of Development Studies at the University of Sussex. The Institute was founded a year ago by the Ministry of Overseas Development and is intended to engage in teaching and research linked with problems of development in countries overseas. It is an autonomous institute sited on the campus of the university.

MR. J. P. EBERHARD has been appointed director of the National Bureau of Standards Institute for Applied Technology on the resignation of Dr. D. A. Schon, who has left to direct the Organization for Social and Technical Innovation, Cambridge, Mass. Mr. Eberhard has been deputy director of the Institute since its establishment in 1964. Dr. L. M. Kushner, former chief of the NBS Metallurgy Division, has been appointed deputy director.

DR. C. M. SINGH, dean of the College of Veterinary and Animal Sciences, Punjab Agricultural University, Hissar, has been appointed director of the Indian Veterinary Research Institute, Izatnagar and Mukteswar. Dr. M. R. Dhanda has been appointed dean of the new Veterinary Faculty at the Agricultural University, Hyderabad.

THE Medical Research Council is assisted in the formulation and execution of its research programme by three advisory Boards which cover the main fields of its work, and have the principal function of overseeing the progress of work supported by the Council and advising on proposals for such support in their respective fields. The following have been appointed to the Boards by the Council: *Biological Research Board*, Dr. D. E. Broadbent (M.R.C. Applied Psychology Research Unit, Cambridge); Prof. W. T. J. Morgan (Department of Biochemistry, Lister Institute of Preventive Medicine); *Clinical Research Board*, Prof. D. A. K. Black (University Department of Medicine, The Royal Infirmary, Manchester); Prof. R. S. Illingworth (Department of Child Health, University of Sheffield); *Tropical Medicine Research Board*, Prof. B. G. Maegraith (Department of Tropical Medicine, Liverpool School of Tropical Medicine); Dr. C. E. Gordon Smith (Microbiological Research Establishment, Porton, Wilts). Prof. W. D. M. Paton has been appointed chairman of the Biological Research Board, in succession to Prof. A. Neuberger.

Announcements

THE Deutsche Akademie der Naturforscher Leopoldina, Halle, recently elected the following new members in the sections indicated: *Physiology*, Prof. H. Drischel (Leipzig); Prof. L. Lubinska (Warsaw); *Physiological Chemistry*, Dr. E. Mikulaszek (Warsaw); *Orthopaedics*, Dr. M. Jaroš (Prague); *Surgery*, Prof. J. J. Navrátil (Brünn); Prof. B. W. Petrovskij (Moscow); *Physics*, Prof. E. Hückel (Marburg); *Chemistry*, Prof. E. Schmitz (Berlin); Prof. K. Schreiber (Gatersleben); Prof. F. Sondheimer (Cambridge). *Mineralogy, Petrology and Crystallography*, Prof. J. Wyart (Paris).

A SYMPOSIUM on "Potential Industrial Applications for Isotopic Power Generators" will be held at the Atomic Energy Research Establishment, Harwell, during September 28–30. Further information can be obtained from the Post Graduate Education Centre, Building 455, A.E.R.E., Harwell, Didcot, Berkshire.

THE eighteenth Pittsburgh Conference on Analytical Chemistry and Applied Spectroscopy, Inc., will be held at the Penn-Sheraton Hotel in Pittsburgh, Pennsylvania, during March 6–10, 1967. Further information can be obtained from Dr. Gerald L. Carlson, program chairman, Eighteenth Pittsburgh Conference, Inc., Mellon Institute, 4400 Fifth Avenue, Pittsburgh, Pennsylvania.

AN international symposium on "Marine Geodesy, Present and Future", sponsored jointly by the U.S. Coast and Geodetic Survey and the Columbus Laboratories of Battelle Memorial Institute, will be held in Columbus, Ohio, during September 28–30. Further information can be obtained from A. G. Mourad, Columbus Laboratories, Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio.

CORRIGENDUM. In the communication entitled "Effect of Altered Perfusion Rates on the Retention of Noradrenaline by the Spleen", by Dr. D. M. Paton and Prof. C. N. Gillis, which appeared on p. 391 of the October 23, 1965, issue of *Nature*, in line 2 of p. 392, "4·8 mg/ml." should read "4·8 ng/ml.", and in the last line of Table 1 "weighted ± test" should read "weighted *t* test".

CORRIGENDUM. In the article entitled "Uptake of Potassium at Low Temperatures in Kidney Cortex Slices of Hibernating Mammals", by Prof. J. S. Willis, which was published on p. 691 of the November 14, 1964, issue of *Nature*, the concentrations of inhibitors used were incorrectly stated (p. 692, column 1, lines 46, 47; Table 1, lines 4, 5 of legend). These should have read "dinitrophenol (0·2 mM) and iodoacetate (1·0 mM)" instead of 0·02 mM and 0·1 mM, respectively.

CORRESPONDENCE

Stonehenge

SIR,—Prof. Hoyle's authority in cosmology is unquestionable and his theories about the use of Stonehenge are ingenious and mathematically sophisticated—perhaps too sophisticated for the culture which produced it. Unfortunately, the same cannot be said of his speculations, which must appall anyone with the slightest acquaintance with the archaeology and history of religions, that the assumed use of the Aubrey holes perhaps gave rise to the idea of Trinity and the concept of an unseen God.

2,000 B.C. is the earliest date assigned to Stonehenge and some authorities date it somewhat later. The worship of the neolithic Mother Goddess, whose cult was widespread over the Western world, and to which Stonehenge is linked through the megalithic tradition associated with it, is dated, in origin, not later than 7,000 B.C. Her triple aspect associated with the ancient three-season year, presumably in use by the builders of Stonehenge, seems to have been the protohistorical origin of the three-in-one concept of Trinity, long before the Bible or Stonehenge. So any symbolic significance the number three might have would be derived from the old religious tradition, and not the other way round.

Hampstead, N.W.3.

COMPUTERS FOR BRITISH RESEARCH

THE formation of the Computer Board by the Secretary of State for Education and Science has not brought a great wave of congratulation from British universities and research establishments, but instead a tendency to complain that it is not enough, and not soon enough. Even the fact that Mr. Anthony Crosland has somehow persuaded the Treasury to part with £3 million a year at a time like this has not silenced all the critics. This may therefore be the right time to ask what are the prospects for computers in the universities and other research establishments in Britain.

The origins of current arguments about the scale on which computing facilities should be provided in British universities go back to the appointment in March 1965 of a working group under Prof. B. H. Flowers. The working group itself was born of discussions within the Council for Scientific Policy (under Sir Harrie Massey), and between the council and the University Grants Committee. Professor Flowers is himself a member of Sir Harrie Massey's committee. His working group moved quickly, and reported to the Minister in July 1965. The report was eventually published in December 1965, together with a general statement by the British Government that its recommendations had won "general approval".

The essential feature of the recommendations was that computing facilities at universities and research establishments should be integrated into a regional framework, with universities and research councils having access as of right to whatever facilities are available. Edinburgh, Manchester and London were singled out as regional centres, to be equipped with powerful computers (rented in the first instance from suppliers in the United States) with the possibility that other universities in the Midlands and South-West might graduate into regional centres later on. It was also argued that money should be spent immediately on making the fullest use of the English Electric *KDF* 9 computers at seven British universities.

Finally, the working group argued the case for spending money on a number of installations at a further twenty-one institutions, either to improve existing machines or to buy new ones. All these developments, according to the report, should be carried out on a regional basis, with universities and the research institutions responsible to the five research councils having a right to use all nearby computers and the regional computing centre.

The estimates in the Flowers Report on future demand for computing power are based on estimates by the universities themselves, though the working group did on some occasions point out that demand was likely to grow more quickly than universities themselves foresaw. Its estimates are, however, supported by the experience of large university installations in the United States where the demand for computer time appears to have been doubling every year for some years now. Taking the computing power of an IBM 7090 as a yardstick (which means that an improved *KDF* 9 with a 36*K* store is equivalent to 1·2 7090 machines), the group estimated that its proposals would increase the computer power of British research institutions from roughly 15 units in March 1965 to roughly 135 in March 1970.

The response of the British Government to these proposals has been surprisingly openhanded, given the economic difficulties of the past twelve months. The total cost of the programme has, however, been stretched out over six years and not five. Orders for the improvements intended at the *KDF* installations and the other twenty-one universities with less sophisticated equipment have already been placed, chiefly through a panel of the University Grants Committee under Sir Willis Jackson. Moreover, a regional centre at Edinburgh has already been formed.

Why, then, has the whole project encountered widespread criticism in recent weeks? Three separate lines of complaint are evident. First, people complain of the delay, both in setting up the computer board and in implementing the other proposals of the Flowers Group. Then there is a complaint that in the interval between the report a year ago and the present, multiple access computer systems have been shown in the United States not to be fanciful experimental tools but essential building bricks in any modern computer system, so that the degree of integration implicit in the Flowers proposals is now inadequate. Finally, it is held that the preoccupation of the Flowers Report with the needs of universities and research councils has made even sharper the gulf between the comparatively academic affairs of the Department of Education and Science and the more industrial preoccupations of the Ministry of Technology.

The nub of the argument on delay is that the investments proposed by the Flowers Group were intended to be spent in the period July 1965 to July 1970, while the present plans of the Government would start a year later and finish two years later. Moreover, the criticism continues, the delay in the setting up of the Computer Board has meant further delays in beginning serious work on the proposals. The rejoinder to this is that Sir Willis Jackson and his panel have been hard at work spending their £3 million a year on the improvement of university computing, and that the panel has even gone somewhat further than the Flowers Group foresaw by placing a firm order for an English Electric multiple access computer at Edinburgh for delivery in roughly two years.

On the character of the computing system to be developed there seems to be genuine disagreement. There are those who argue that the time has now come for a closely integrated system of computers within a national network, with access by means of individual consoles. It is held that experience in the United States, and the character of forward planning in France, make such a system feasible and desirable in Britain. On the other hand are those who argue that the experience with systems such as Project MAC at the Massachusetts Institute of Technology (*Nature*, 209, 1161; 1966) is not yet sufficient to demonstrate that a multiple access system on a national scale will really work. In any event, they argue, the universities and research establishments will always need a much more personal form of access to computers, for their need of these machines is not simply their need of computation but also their need of opportunities for teaching and research.

The complaint about the gulf between science and technology is linked with the way in which the Ministry of Technology is apparently pursuing an independent policy in the development of computing centres. Thus it has recently established a National Computing Centre at the Manchester College of Science and Technology, with Professor Gordon Black as director. The centre will be a more or less commercial venture, drawing support by way of fees from industrial manufacturers and users of computers, and also by means of grants from the Ministry of Technology. The decisive role of the centre can be in the development of software both for use with machines now being developed by British companies and for improving the efficiency of systems already in use.

DID THE ATLANTIC CLOSE AND THEN RE-OPEN?

By PROF. J. TUZO WILSON

Institute of Earth Sciences, University of Toronto

FOR more than a century it has been recognized that an unusual feature of the shallow water marine faunas of Lower Palaeozoic time is their division into two clearly marked geographic regions, which are commonly referred to as faunal realms. "The faunal assemblages are amazingly uniform throughout each realm so that correlation of any Cambrian section with another in the same realm is usually easy; on the other hand, the difference between the faunas in the two separate realms is so great as to make correlation between them very difficult"[1].

Two aspects of the distribution of these realms are remarkable. For one thing, some regions of similar faunas are separated by the whole width of the Atlantic Ocean; then, on the other hand, some regions of dissimilar faunas lie adjacent to one another. This is illustrated by Fig. 1, which is based on work by Cowie[2], Grabau[3] and Hutchinson[4].

Grabau showed that, if Europe and North America had become separated by continental drift, a simple reconstruction could explain the first anomaly in the distribution of the faunal realms in that, before the opening of the Atlantic Ocean, each realm would have been continuous, with no large gaps between outcrops of similar facies (Fig. 2).

It is the object of this article to show that drift can also explain the second anomaly. It is proposed that, in Lower Palaeozoic time, a proto-Atlantic Ocean existed so as to form the boundary between the two realms, and that during Middle and Upper Palaeozoic time the ocean closed by stages, so bringing dissimilar facies together (Fig. 3). The supposed closing of the Tethys Sea by northward movement of India into contact with the rest of Asia, and the partial closing of the Mediterranean by northward movement of Africa, can be regarded as a similar but more recent event. The figures are based on a reconstruction by Bullard, Everett and Smith[5], but because those authors pointed out that no allowance had been made for the construction of post-Jurassic shelves, the continents have been brought more closely together.

Four lines of evidence suggest that this proposal is reasonable. (Unfortunately, so far as I can ascertain, palaeomagnetic evidence which might bear on this problem does not exist.)

First, this reconstruction of geological history is held to provide a unified explanation of the changes in rock types, fossils, mountain building episodes and palaeoclimates represented by the rocks of the Atlantic region.

Second, wherever the junction between contiguous parts of different realms is exposed, it is marked by extensive faulting, thrusting and crushing.

Third, there is evidence that the junction is everywhere along the eastern side of a series of ancient island arcs (Fig. 3).

Fourth, the fit appears to meet the geometric requirement that during a single cycle of closing and

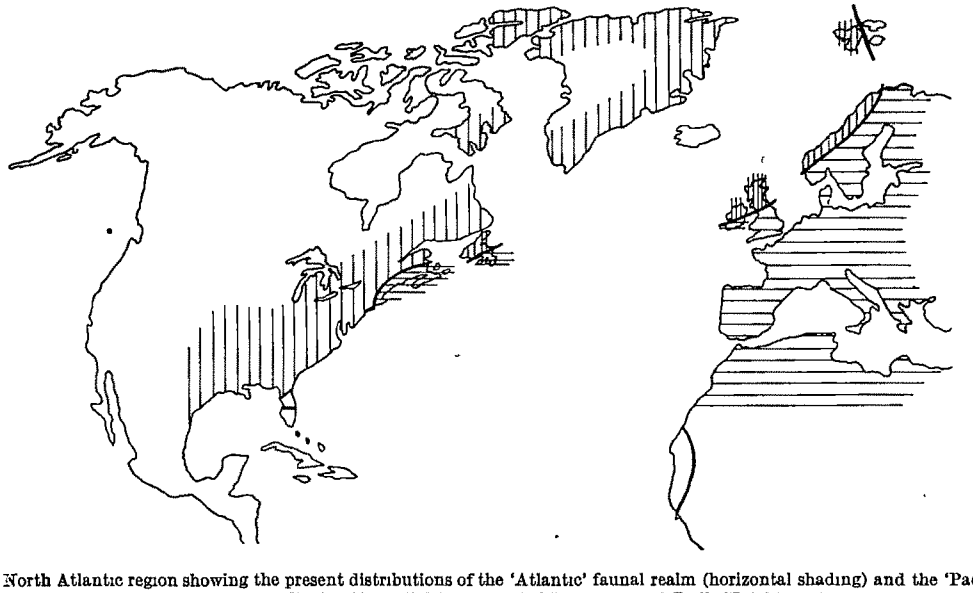

Fig. 1. The North Atlantic region showing the present distributions of the 'Atlantic' faunal realm (horizontal shading) and the 'Pacific' faunal realm (vertical shading). (After J. W. Cowie, A. W. Grabau and R. D. Hutchinson)

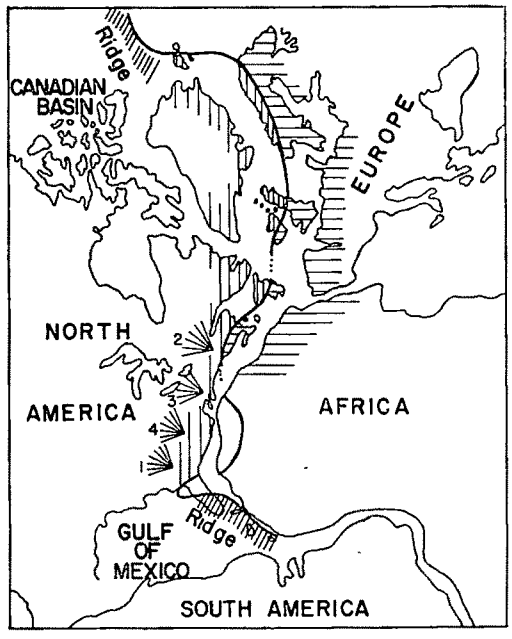

Fig. 2. The North Atlantic region in Upper Palaeozoic and Lower Mesozoic time showing that of the present Atlantic Ocean only the Canadian Basin and the Gulf of Mexico then existed. Four fans are shown which were formed: (1) during Middle Ordovician; (2) during Upper Ordovician, (3) during Upper Devonian; (4) during Pennsylvanian. The heavy line separates 'Pacific' and 'Atlantic' faunal realms. The two ridges are considered to have formed when the modern Atlantic started to open

reopening of an ocean, and in any latitudinal belt of the ocean, only one of the pair of opposing coasts can change sides (Fig. 4).

Recurrent Drift in the North Atlantic

The history proposed for the North Atlantic region can be stated very briefly as follows: (*a*) From the Late Pre-Cambrian to the close of Middle Ordovician time an open ocean existed in approximately, but not precisely, the same location as the present North Atlantic (Fig. 3). (*b*) From the Upper Ordovician to Carboniferous time, this ocean closed by stages. (*c*) From Permian to Jurassic time there was no deep ocean in the North Atlantic region. The only marine deposits of that time are those connected with the Tethys Sea, with a shallow Jurassic invasion of Europe and with deeper Jurassic seas in the Gulf of Mexico and in the western Arctic Basin (Fig. 2). (*d*) Since the beginning of the Cretaceous period the present Atlantic Ocean has been opening, but this reopening did not follow the precise line of junction formed by the closing of the early Palaeozoic Atlantic Ocean; the result is that some coastal regions have been transposed (Fig. 1).

The Lower Palaeozoic continents may have first touched each other at the end of Middle Ordovician time, for thereafter the distinction between 'Atlantic' and 'Pacific' faunal realms ceases to be marked, but the complete closing of the ancient Atlantic may have required several periods.

For each continent, union meant replacing the open ocean by the other continent. This is offered as an explanation of the borderlands of J. Barrell and C. Schuchert for which there is no clear evidence until Upper Ordovician time. As Kay has suggested[6] concerning Eastern North America: "There has been little discussion of the evidence for borderlands in earlier Paleozoic time, though some have expressed scepticism". Kay's own support for island arcs is muted after Lower Palaeozoic time and he accepts the view that the sediments of the "Late Devonian and Early Mississippian came from the land of Appalachia", —a borderland.

This view that extensive upland source areas lay to the east of the Appalachian geosyncline in the sites of the present coastal plain or ocean has been fully supported by recent work[7–9]. Tens of thousands of cubic miles of quartz-rich sediments, derived from the east, were deposited in shallow marine to sub-aerial deltas.

When the continents were pushed together, they would have touched first at one promontory and then at another. It can be expected that high mountains would have been formed locally and that they would have produced alluvial fans on both continents. As the ocean diminished the climate would have become increasingly arid. Such drastic alterations in the physiography would explain the change from predominantly marine and island arc deposition in the Lower Palaeozoic to conspicuous fans of Queenston, Catskill, Old Red Sandstone, and other deltas of Middle and Upper Palaeozoic time (see refs. 10 and 11, and Fig. 2). It can also be expected that the collision of continents would have produced great local uplifts which, if one continent overrode the other, would have migrated inland, perhaps pushing the Taconic and northern Newfoundland klippen[12] before them.

It would seem that by Permian and Triassic times the Atlantic Ocean was completely closed, because only continental beds, such as the Dunkard and Newark series, are found in North America. In Great Britain the New Red Sandstone is also continental as is the Permian of the Oslo district.

No Jurassic beds are known in eastern North America except in the Gulf of Mexico. Those of Europe were formed by a shallow marine invasion of the continent and are said by Hallam[13] to have fossils that "include many neritic forms that could not have crossed a deep ocean. The paleogeography for the Scottish Jurassic gives no hint of increasingly marine conditions to the west" (personal communication). Most of the available geological evidence suggests that the present Atlantic Ocean started to open at the beginning of Cretaceous time[14,15]. Although objections to this view are still being raised, they seem to be minor in comparison with the other evidence, and it is possible that they can be explained in other ways.

Faulted Contact between Faunal Realms

Starting our considerations in the north, the island of West Spitsbergen is underlain by a thick eugeosynclinal section of Lower Palaeozoic rocks named the Hecla Hoek succession. These strata rest on no known basement and were deformed, metamorphosed and intruded by granites during the Caledonian orogeny[16,17]. They contain fossils of the 'Pacific' fauna similar to those of Scotland and North America[18].

In Nordaustlandet, the adjacent, eastern island of the Spitsbergen group, Kulling[19] and Sandford[20] have mapped a thin section of unmetamorphosed and gently folded strata which a few fossils indicate to be of about the same age. These beds lie uncomformably on a basement which is regarded as part of the Baltic Shield. These strata do not thicken to the west as the much thicker section of West Spitsbergen is approached, nor do the few fossils necessarily belong to the 'Pacific' faunal realm.

Despite the considerable number of attempts to compare the sections in the adjacent islands, the correlation is not good. Changes in thickness, facies, and degree of metamorphism, basement and type of intrusives are all abrupt and striking. Orvin[21] and others have mapped faults in Hinlopen Strait between the islands. Klitin[22] summarizes the situation thus: "Of particular interest is the junction zone of the alleged Caledonian platform and Caledonian fold system. The transition to typical caledonids takes place in a zone not over 15 to 20 km wide, in the Hinlopen

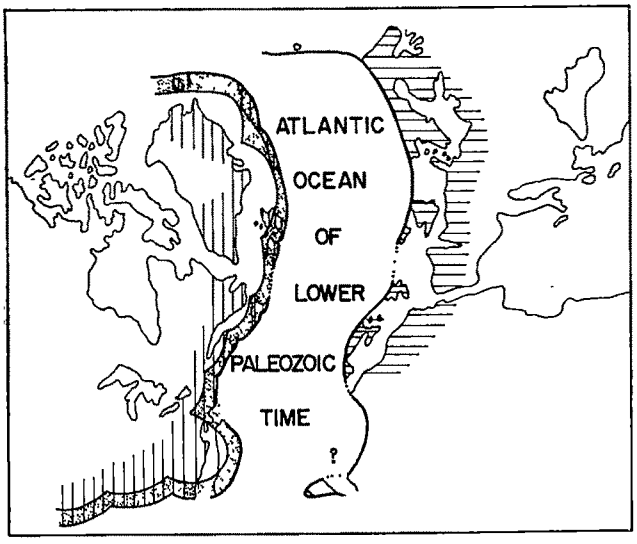

Fig. 3. The North Atlantic region in Lower Palaeozoic time. The proto-Atlantic Ocean would have formed a complete barrier between two faunal realms (shaded). Island arcs (dotted) probably lay along the North American coast. The floor of this ocean could have been absorbed in the trenches associated with these arcs as the ocean closed

Strait area, where the Hecla Hoek section abruptly increases in thickness, by a factor of four, with the appearance of extrusives in its metamorphosed and linearly folded beds. Such radical changes in thickness suggest a fault junction between an ancient platform and the caledonids." Following this interpretation I suggest that the Lower Palaeozoic ocean once separated the two islands and that, whereas Nordaustland formed part of the Baltic shield and shelf, West Spitsbergen was the site of a North American island arc.

In Scandinavia it is well established that the peninsula is divided longitudinally into two different provinces separated by a great zone of nappes and faults overthrust towards the east. According to the descriptions of Holtedahl[23], south-eastern Norway and most of Sweden are underlain by an extension of the Baltic Platform on which lie nearly flat, unfossiliferous rocks and "the eastern facies of the Cambro-Silurian (which) can be classed as miogeosynclinal in the terminology of Stille. The thickness is rather large and there is much terrigeneous material. Caledonian volcanic and intrusive igneous rocks are not found in the deposits of this type. The rocks are unmetamorphosed in the east and are of low metamorphic grade farther to the north-west. The deposits occur in an autochthonous or parautochthonous position above the original Archean basement."

The fossils are repeatedly referred to as being similar to those of the Baltic region, England and Wales. On the other hand, in the Trondheim area of western Norway, a thick succession of pillow lavas, shale and limestone with serpentinites in the lower part of the sequence contains a fauna "of American affinities . . . the limestone of Smøla is similar to the Durness in Scotland and to more or less contemporaneous limestone in Newfoundland, Bear Island and Spitsbergen. The limestone in Smøla thus seems to represent an American-Arctic facies of the Ordovician." In these "mainly pelitic sediments . . . we thus have a eugeosynclinal facies characteristic of the central parts of a geosyncline . . . probably all rocks of the present facies occur in allochthonous positions." An important event in central southern Norway was the close of marine deposition "in Late Ordovician or Early Silurian time brought about by the thrusting of nappes and deposition of the Valdres sparagmite (arkose), which was considered as a deposit of flysch type by Goldschmidt". The zone of nappes is, therefore, held to be the boundary between faunal provinces and the line of closure of the Lower Palaeozoic ocean.

The geological relationship between Spitsbergen, Scandinavia and the British Isles has been discussed by Bailey and Holtedahl[24]. Of the Caledonian structures they state: " . . . in the present land area of Scandinavia we find the eastern part of the orogenetic belt only, while in Great Britain the whole of the orogenetic zone is represented. The Spitsbergen Group seems to lie rather centrally in the zone of deformation." Following Wegener, they consider that Greenland may have been formerly connected with Europe and suggest that, if so, it would have completed the western side of the mountain belt opposite Norway. This relationship has found support in recent years from several authors[14] including Umbgrove[25].

That the boundary between 'Atlantic' and 'Pacific' faunal realms crosses northern England between Scotland and Wales is supported by Walton, who writes of the Scottish occurrences: "The close affinity of the Durness and North America rocks was recognised long ago . . . . The long-recognised affinity of the Girvan Caradocian and Appalachian Mohawkian faunas was re-emphasized by Williams . . . . By contrast the faunas are only remotely connected with the Welsh Ordovician rocks"[26]. George[27] describes the relations thus: "The Salopian geosyncline may thus have extended unbrokenly from conjectural north-western limits in the Highlands to a south-eastern margin or marginal shelf in the English Midlands". It does not require much change to regard this geosyncline as a former ocean.

In Newfoundland the geology of the north-eastern coast has recently been described by Williams[28]. He suggests that in Cambrian time a deep basin or ocean, not underlain by continental crust, crossed the central part of the island and separated two shelves. The north-western shelf underlying the Long Peninsula has a basement of Grenville age overlain by strata with 'Pacific' faunas like those of Scotland, while the south-eastern shelf, which forms the Avalon peninsula, has a younger Pre-Cambrian basement overlain by strata with 'Atlantic' faunas like those of Wales. During Ordovician and subsequent time the intervening sea became filled with eugeosynclinal and volcanic sedimentary rocks, probably representing a former island arc and mountain belt.

Anderson[29] believes that faulting in Hermitage Bay on the south coast of Newfoundland not only separates the rocks of the south-eastern shelf from the central geosyncline, but may also completely divide the two faunas. On the north coast the corresponding fault zone may be in Freshwater Bay, but this point has not been settled as yet[30].

Among those who have recently correlated the Newfoundland and British sections are Dewey and Church[31]. Although Church does not favour continental drift, both he and Dewey make the same correlation as that already given here and extend the Caledonian mobile belt from northern England and central Ireland to central Newfoundland.

South of Newfoundland, the Gulf of St. Lawrence and younger rocks cover the key areas of Lower Palaeozoic formations almost as far as the Maine border. Little can be said except that the faunas of Cape Breton Island and St. John, New Brunswick, have European affinities while those of Gaspé and the Eastern Township of Quebec are typical of Scotland and most of North America[4].

In northern and eastern Maine the older literature is sparse and generalized. Recently a combined group of government and university geologists, including W. B. N. Berry, A. J. Boucot, E. Mencher, R. S. Naylor and L. Pavlides, have discovered new fossil localities there with both European and North American affinities, important Caledonian uplifts and large pre-Silurian faults[32]. Much

of the state has been remapped, but for the reason that little of this work has yet been published (R. G. Doyle, personal communication), and because the structure is clearly much more complex than shown on early maps, this is not an opportune time to consider the area in detail.

From the southern part of Maine south across New Hampshire, Massachusetts and Connecticut a major zone can be traced from published accounts. Novotny[33] has described this "major fault zone" where it crosses the New Hampshire–Massachusetts boundary (Fig. 5). To the north it connects with several faults and silicified zones shown on the map of New Hampshire[34,35]. These lie along the line which separates those formations which underlie the greater part of New Hampshire from a suite of completely different formations, underlying south-eastern New Hampshire. This line may be continued northward into south-eastern Maine by the faults which Katz[36] has suggested bound the Berwich gneiss, itself crumpled, "closely folded and overturned". In Massachusetts, Novotny's fault may be exposed in the abandoned Worcester "coal" mine. The description suggests that much of the rock may be carbonaceous mylonite[37]. South of Worcester this fault connects with a major change in formations evident on the geological map of Massachusetts[38].

In Connecticut this boundary appears to join the Honey Hill fault and its northern continuation which bisect the state and separate two major rock sequences. Where best described in the south it "has been mapped for 25 miles eastward from Chester nearly to Preston without apparent repetition of the stratigraphy on either side of the fault. The fault plane dips 10°–35° N parallel to the underlying metasedimentary rocks .... The fault is marked by a zone a mile wide of mylonitized and crushed rocks .... Displacement must have been many miles"[39]. As in Norway, the orogenic belt appears to have been thrust eastwards over the eastern platform. To the south this major fault seems to strike into the Atlantic Ocean and the Appalachian belt, then narrows conspicuously. I have recently learned from L. R. Page and J. W. Peoples that mapping (for the most unpublished) by the federal and state surveys has defined this fault zone more satisfactorily, and that published aeromagnetic maps show a change in the strike of anomalies across it. This evidence suggests that New England is divided by a major fault zone into two provinces underlain by quite different rock formations. Of the few occurrences of the Lower Palaeozoic faunas, all those with European affinities lie to the east of the fault zone; all those typical of North America to the west[40,41].

In the light of this evidence it seems reasonable to suggest that this fault zone marks the line of closure of the Lower Palaeozoic Atlantic Ocean. It may seem strange to propose that a former position of the Atlantic Ocean lies through New England and that its full significance has not been realized, but it must be remembered that throughout the area outcrops are poor and that most of the mapping is old. Surface mapping reveals few faults, but new tunnels have shown that faults abound under the drift-filled valleys and that some of these are major (J. W. Skehan and A. Quinn, personal communications).

Most North American geologists have not accepted the idea of continental drift. Instead they have sought to explain the changes in faunas in terms of different environmental conditions. This has certainly been a factor and no doubt was responsible for the differences between the Durness, Girvan and Moffatt facies in Scotland, although those facies belong to the same faunal realm. In another example, G. Theokritoff (personal communication) has directed my attention to a possible mixing of Atlantic, Pacific and endemic faunas in the Taconic sequence of New York[42]. Christina Lochman[43] has emphasized the difficulties incurred in accepting such an interpretation. She states that the areas of mixed faunas

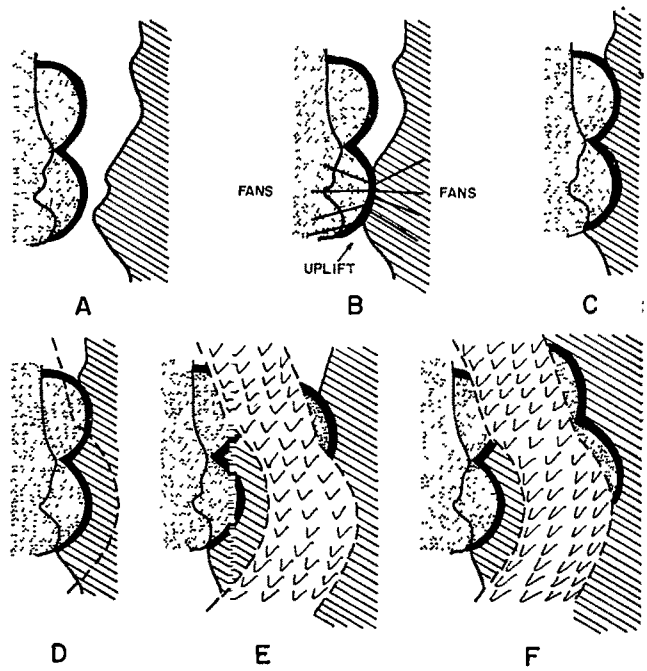

Fig. 4. *A*, A closing ocean, with island arcs on one coast, separating two different faunal realms. *B*, First contact between two opposite sides of a closing ocean. *C*, The ocean closed by overlap of the opposite coasts. *D*, A possible line (dashed) along which a younger ocean could reopen. *E*, A new ocean (checked) opening in an old continent. *F*, A geometrically impossible way for a younger ocean to open. (Note how the arcs overlap.)

lie in deeply down-warped basins between two shallow shelf deposits containing respectively Atlantic and Pacific faunas. These basins, she remarks, had connexions with the Atlantic Ocean and had a benthonic environment "similar to that of the open ocean .... Few normal benthonic species of the coastal shelf could establish themselves in such an alien environment, although, because of the geographic proximity of the two areas, sporadically drifted individuals might be found." She also refers to deep basins separating different faunas and to the evidence for a "biofacies regime ordinarily found on the floors of the continental shelf beyond the inner islands of the volcanic archipelago". These views would seem to admit the possibility of interpreting the palaeogeography as has been done in this article. It is suggested that one of the deep basins, instead of lying on a shelf, might have been an open ocean in Lower Palaeozoic time and that the mixed fauna may have come from the extreme edge of one continent.

The reconstruction (Fig. 2) then leads to Africa. Sougy[44] has described a large plate of metamorphic rocks east of Dakar thrust eastwards over Upper Devonian strata. Farther north in Spanish Morocco there is a folded belt. A large Cretaceous overlap along the coast and lack of diagnostic fossils in the overthrust block make correlation difficult, but Sougy concludes that: "In the future, when geologists study the relationships between America and Africa for evidence bearing on permanence of continents and oceans *versus* continental drift, they will have to consider that the western rim of Africa is made, from Guinea to Morocco, not of a Pre-Cambrian basement but of a mainly Hercynian orogenic belt, in some respects symmetrical to the Appalachian belt." His mention of drift suggests, as do most reconstructions[5], that this West African belt was formerly part of the Appalachians. This view is supported by P. A. Mohr, who writes: "the Cambrian manganese ores of Newfoundland, Wales and Morocco ... I think were formed in a common geosynclinal trough" (personal communication). The view that these regions were

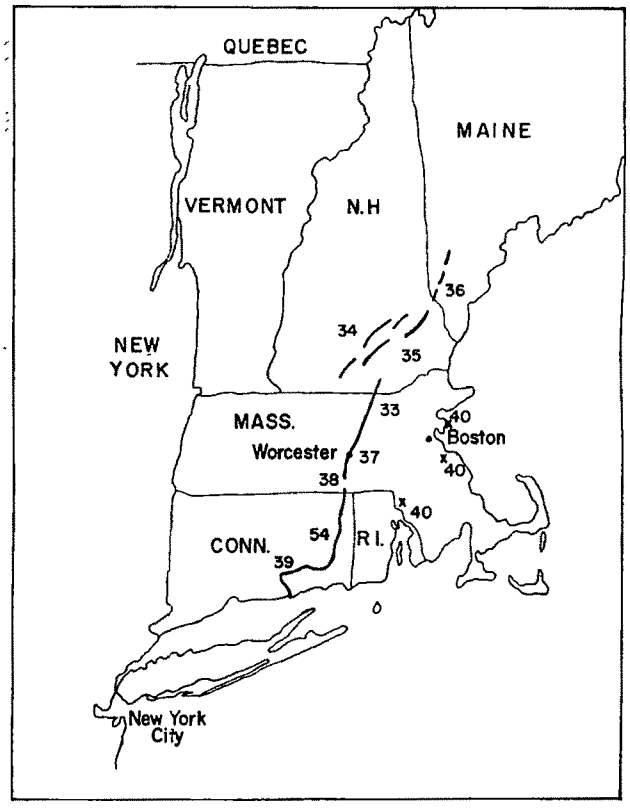

Fig. 5. Sketch map of New England showing location of some major faults and three fossil localities of the 'Atlantic' faunal realm (*X*). The numbers refer to papers in the list of references from which information was obtained

together until Cretaceous time is supported by the close similarity of Cretaceous fossils from these two regions now on opposite sides of the ocean[45]. Only further investigation, aided by extensive seismic investigations or drilling through the Cretaceous of both continental coasts, can show whether it is possible or likely that West Africa ever fitted into the central east coast of the United States. If so, some rotation of Africa clockwise and a closer fit than that shown by Bullard, Everett and Smith[5] may be indicated.

Although the northern termination of the West African fold belt is covered, its termination to the south is definite; the Pre-Cambrian of the African Shield extends to the Atlantic near Conakry[46]. The reconstruction suggests that this contact might reach Florida. In Florida and Georgia a cross-section of the Appalachians resembles that of Newfoundland in that these are the only parts of the Appalachians with a platform on both sides of the mobile belt. The platform on the south-eastern side of the mobile belt which lies beneath northern Florida and adjacent states is only known from well cores. These consist of Early Ordovician to Middle Devonian sandstones and shales said to have been deposited in shallow water[47]. Published accounts do not correlate the strata or fossils with formations elsewhere. It would seem that the basement has not been penetrated. Thus it is only speculative to suggest that this region was formerly part of Africa.

Island Arcs of Lower Palaeozoic Atlantic

According to a widely adopted hypothesis, island arcs and mountains represent places where the lithosphere is being compressed, while mid-ocean ridges represent places where it is being pulled apart and where new crust is being created. Thus the present Atlantic Ocean is expanding from the Mid-Atlantic Ridge.

For a Lower Palaeozoic Atlantic Ocean to have closed, it must, according to this hypothesis, have been marked not by a central ridge, but by a continuous system of island arcs and mountains. Observation shows that such systems commonly lie at the sides and not in the centre of oceans. Kay's view, that a system of island arcs existed off the eastern and southern coasts of North America in Lower Palaeozoic time, is entirely compatible with this hypothesis. This would have allowed the former Atlantic Ocean to close, and thus to convert the offshore island arcs of Lower Palaeozoic time into the intercontinental Appalachian mountains of Middle and Upper Palaeozoic time. Following Keith, Kay and King, I have sketched the location of seven former arcs in the Appalachians and their south-western continuation past the Ouachita and Marathon Mountains[48]. I see no reason to change this view.

The situation in Scotland has been described by Walton: "It seems likely that both the north-west Highlands and the Appalachians formed part of a very wide stable shelf which also included Greenland and other 'Boreal' regions having very similar Cambrian rock types. . . . it is probable that sedimentation in the area of the southern Highlands during the Cambrian period was mainly of a greywacke, geosynclinal type and contrasted strongly with that in the north-west Highlands . . . it is probable that Cambrian sedimentation stretched unbroken to an unknown distance south of the Highland Boundary fault"[26]. Ordovician volcanism followed and these correlations and descriptions suggest that, during Lower Palaeozoic time, arcs associated with a western land extended across Scotland. That there may have been contemporaneous volcanism and islands along the eastern coast in what is now Wales, merely adds complexity without affecting the history in Scotland. In the Silurian period conditions changed and the marine conditions "gave way to mixed environments . . . at least partly in fluvio-deltaic environments with periods of emergence"[26].

Enough has been described of the conditions in Norway and West Spitsbergen and of their correlations with Scotland to show that they too were the sites of Lower Palaeozoic island arcs associated with a western continent. Thus the Caledonian–Appalachian arcs seem to have formed a continuous system along the western side of the former ocean. It is suggested that it was in the trenches of these arcs that the floor of the Lower Palaeozoic Ocean was swallowed up as that ocean closed.

Geometrical Control of Transposition

If two bodies are brought together so that they unite, and if they are later pulled apart so that they break on a different line from the line of union, then one important geometrical consideration holds. It is that, along any one stretch of the junction, only one fragment can change sides: one cannot transpose pieces from each margin at the same place. This is illustrated in Fig. 4 and a comparison with the other figures shows that our reconstruction obeys this principle. This does not prove that the reconstruction is correct, but the neat fashion in which fragments from either side are alternately transposed meets the geometrical requirements.

Some Possible Extensions

When, as is believed, the present Atlantic Ocean started to open at the beginning of Cretaceous time, it did so by breaking open a continent which was then continuous from West Spitsbergen to Florida (Fig. 2). North of Spitsbergen the coasts of North America and Siberia at that time diverged and the opening ceased to lie wholly within a continent and to have continental blocks on both sides. Following the descriptions of B. C. Heezen

and M. Ewing, and Ya. Ya. Hakkel and N. A. Ostenso, I have suggested that the fracture followed the coast of Siberia forming the Lomonosov Ridge on the other side of the opening. Thus the Lomonosov Ridge separates an older Canadian ocean basin from a younger Siberian ocean basin in the Arctic Sea[14].

In the south the situation appears to be similar, but to understand it one must clearly separate the platform of northern Florida from the different geology of southern Florida. South of central Florida a southern Florida–Bahamas Ridge separates a main Atlantic, apparently of Cretaceous age, from a Gulf of Mexico which seems to have been a deep ocean and evaporite basin during the Jurassic period.

Drake, Heirtzler and Hirschman[49] emphasize the importance of the Florida-Bahamas Ridge for sealing off the Gulf of Mexico from the open ocean so that the Jurassic salt deposits could form. They suggest that this ridge is an "extension of the Ouachita system" and that it forms the "foundation for the entire chain of islands and banks". This ignores the earlier interpretations of magnetic and gravity anomaly maps made by Miller and Ewing[50] and by Lee[51]. Both papers suggested that southern Florida and the Bahamas are coral banks built on deeply submerged volcanoes. The Palaeozoic platform-type of sedimentary rocks, described from drill cores in northern Florida, are not like the Ouachita folds. Drilling has revealed no Palaeozoic rocks beneath southern Florida and the Bahamas. The magnetic anomaly map shows a marked change in central Florida. Drake *et al.*, in their Fig. 5, show three trend lines connecting southern Florida with the Bahamas and only one connecting it with northern Florida. It is suggested that the Florida-Bahamas Ridge, like the Lomonosov Ridge, formed when the main Atlantic Ocean started to open at the beginning of Cretaceous time and separated an ocean basin of Cretaceous age from an older ocean basin.

Drake *et al.* hold that the Florida-Bahamas Ridge extends to Navidad Bank, north of Hispaniola. It thus ends at the major zone of faulting which, according to Hess and Maxwell[52], and others, extends from Central America to the northern end of the West Indies arc. The Caribbean Sea and West Indies arc have often been regarded as associated with the Pacific Ocean, and I have discussed elsewhere their possible origin as a tongue, thrust from the Pacific and bounded by transform faults[53].

A complete discussion would require consideration of the Hercynian orogeny and faulting and post-Triassic faulting. This seems feasible but will not be attempted here.

It has been suggested in this article that during Lower Palaeozoic time North America and Europe were approaching each other, that this motion stopped and that it later reversed. If this is true, the onset of the reverse motion and the start of reopening of the Atlantic Ocean must have been an event of very major significance in world geology. The evidence suggests that it occurred at about the close of the Jurassic and the beginning of the Cretaceous periods. It seems reasonable to link it with other major events of that age in the Americas.

McLearn[55] has pointed out that at that time the drainage of much of western North America reversed its direction so that rivers which had been flowing west and building a great shelf along the Pacific coast were interrupted by the rise of the Cordillera and began to follow their present directions. Gilluly[56] has pointed out that "In Cretaceous time plutons probably a thousand times larger than those of all the rest of the Phanerozoic were emplaced". The onset of a relative advance of the Americas over the Pacific Ocean floor might well have caused a crumpling of the shelves along that coast with the creation and rise of extensive batholiths. Gilluly has pointed this out and concluded that the likely cause was that "it is probable that the continent as a whole is moving away from a widening Atlantic".

I am happy to acknowledge the benefits of discussions with W. B. Harland, A. Hallam, J. Dewey, W. R. Church, F. D. Anderson, H. Williams, E. W. R. Neale, H. H. Hess, F. J. Vine, E. Irving, A. Quinn, T. Mutch, J. Sougy and others, and of correspondence with many. I also thank F. W. Beales, C. Harper and D. York for help with the final version of this article.

BOOK REVIEWS

RADIOACTIVE FALL-OUT

Radioactive Fallout from Nuclear Weapons Tests
Edited by Alfred W. Klement, jun. (Proceedings of the Second Conference, Germantown, Maryland, November 3–6, 1964. AEC Symposium Series 5.) Pp. ix + 953. (Oak Ridge, Tennessee: U.S. Atomic Energy Commission, 1965. Available from Clearinghouse for Federal Scientific and Technical Information, National Bureau of Standards, U.S. Department of Commerce, Springfield, Virginia.) 6.50 dollars.

THE second fall-out conference at Germantown was convened by the U.S. Atomic Energy Commission in November 1964. The size of the programme of about sixty papers presented by research groups sponsored by the Atomic Energy Commission indicates the magnitude of the sponsor's interest and investment in the subject.

The conference took place 2 years after the end of the second phase of massive nuclear testing during 1961–62 and was aimed at "elucidating fallout mechanisms from the source of nuclear debris to its contact with man". The scope was therefore large, ranging from the fractionation of fission products and the formation of particles in the explosion, through atmospheric transport over short and long distances, atmospheric storage and transfer, observation of the concentrations of radioactive debris at altitude and near the surface, to deposition on the ground and incorporation in foodstuff and eventually in man.

The introductory paper by E. C. Freiling on "Nuclear Debris Formation" ascribed the theoretical distribution in the case of a land-surface explosion of the refractory nuclides such as zirconium-95 largely to local deposition, and the more volatile mass-chains, represented by caesium-137 and strontium-90, mainly to world-wide fall-out. Qualitatively, agreement with observation was good despite differences in the particle-size distributions. Papers by P. Loysen and P. J. Drevinsky dealt with characteristics of radioactive particles collected at altitudes up to 30 km. Most of the radioactivity is carried on particles of less than $\sim 0{\cdot}1\mu$ diameter with a peak concentration between 15 and 21 km. This is consistent with the altitude of the maximum (number) concentration of natural aerosol observed by Junge, although the size is at the lower end of the natural range. Such particles of nuclear debris from a stratospheric source become associated with relatively large non-active aerosols in the troposphere. This is clearly shown by the results of L. B. Lockhart, who reported a diameter range near ground level between 0·3 and 1μ for an assumed density of 1·8 g/cm^3.

H. W. Feely presented the latest analysis of the stratospheric distribution of strontium-90 based on sampling by aircraft and balloon. He estimated that by January 1964 the stratospheric burden had fallen to 4 Mc. of strontium-90 (from a total production of 19 Mc.). The vertical distribution of strontium-90 and other tracers suggested that little debris had stabilized above 21 km in the polar stratosphere although a movement from the northern to the southern hemisphere had occurred, preferentially in the southern autumn and winter. The paper of L. Machta took a similar global view and summarized the fate of debris injected into the troposphere and stratosphere, the global inventory of strontium-90 and carbon-14 and the partition between the stratosphere, troposphere and Earth's surface. He also discussed the concept of atmospheric residence time—in the simplest treatment apparently variable with time—the validity of an exponential removal rate and the need for theoretical meteorological models to aid prediction. R. E. Newell reviewed the temperature and wind structure of the atmosphere by investigating the interaction between radiative and dynamic processes. It appears that both the mesosphere and lower stratosphere are driven by energy received from the regions immediately below, and that mass transfer in the lower stratosphere is primarily accomplished by large-scale eddy processes, although forced mean circulations arise from these processes.

The fate of cadmium-109 as a specific tracer is described in papers by M. I. Kalkstein and L. P. Salter. There is evidence that this material injected at very high altitude near the equator spread to both hemispheres, as did a portion of the fission products from the more energetic polar injections.

At a lower altitude, E. F. Danielsen developed his concept of "tropopause folding" as a mechanism of exchange between stratosphere and troposphere by showing that layers could form in the troposphere having radioactivity and potential vorticity characteristic of the stratosphere. In the same region of the atmosphere, J. D. Mahlman established a relationship between cyclogenesis at the tropopause and short-period fall-out peaks, although not with the broad spring maxima.

Since 1957, the United States has established an extensive air sampling network roughly along the eightieth meridian. The results of this work were presented by H. L. Volchok, who confirmed that debris was well and rapidly mixed but remained within the northern hemisphere. This implies an effective equatorial barrier to interhemispheric exchange in the lower atmosphere and is contrary to the situation noted for high-altitude injections. The behaviour of the hemispheres was thought to be symmetrical after allowing for a four-month difference in phase, although Danielsen, in discussion, proposed that asymmetry in the lag and in the seasonal variation could be attributed to asymmetry in the land masses of the two hemispheres. This hypothesis may be tested by French nuclear tests in the southern hemisphere, perhaps during 1966. On a much smaller scale, several papers dealt with the cleansing of the atmosphere by rain using intensive rain sampling networks.

The final section of the conference report is concerned with the distribution of radionuclides in food and retention in man. Various empirical formulae were derived to predict fall-out deposition from the concentration in air and also to determine the content in milk. The paper by J. Rivera contained estimates, for residents of New York City, of the strontium-90/calcium ratio in diet and in human bone. The derived bone dose already received from nuclear tests was seen to be very low compared with that delivered from natural radioactivity.

No compilation of conference papers can hope to give a connected and consecutive account of the chosen subject: nevertheless, the Germantown proceedings present to the informed reader a survey of the field. One would have welcomed a discussion of the mechanism of dry fall-out, and a short but authoritative analysis of the hazard to the world's population.

The aims of research into fall-out are really twofold. On the one hand, the objective is to determine the effect on human health and life, and on the other to utilize the nuclear debris as tracers of atmospheric movement. There is probably sufficient information from experimental

observation to assess the effect of fall-out on human life, not absolutely, but in comparison with the effects of natural radiation. On the meteorological side, sampling and measurement have established or confirmed the existence of interesting phenomena such as the seasonal and latitudinal variations of fall-out and provided a measure of the exchange between the hemispheres, but there have as yet been no decisive links with meteorological theory. The *Proceedings of the Second Germantown Conference* reflect the early stages of development of this branch of science by defining, more or less, the problems but not the solutions. D. H. PEIRSON

SYNTHESIZING PEPTIDES

The Peptides

By Eberhard Schroder and Klaus Lübke. Translated by Erhard Gross. Vol. 1: Methods of Peptide Synthesis. Pp. xxix+481. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1965.) 160*s*.

Peptides

Edited by L. Zervas. (Proceedings of the Sixth European Symposium, Athens, September 1963.) Pp. xvi+386. (London and New York: Pergamon Press, Ltd., 1966.) 105*s*. net; $17.50.

THE modern era in peptide synthesis began in 1932, when Bergmann and Zervas introduced the benzyloxycarbonyl ('carbobenzoxy') group for the protection of amino-groups in such syntheses. The subsequent years have seen a remarkable growth of interest in the field and of methods available for the synthesis of peptides. Increased interest in the field has resulted mainly from the discovery of numerous biologically highly active peptide hormones and the desire to synthesize not only the hormones themselves, but also analogues in the hope of finding more active substitutes for, or antagonists to, the natural hormones which might be of value in medicine. Major landmarks in the progress of peptide synthesis during this period include Harington's synthesis of glutathione (1935), du Vigneaud's synthesis of oxytocin (1953) and Schwyzer's synthesis of ACTH (1963). The even more recent syntheses, by groups of workers in China, Germany and the United States, of the two peptide chains of insulin and their oxidative combination to give insulin, albeit only in poor yield, perhaps open a new era which may well see the total synthesis of true proteins, with all that this implies for biochemical knowledge.

To the uninitiated, peptide chemistry may sometimes seem to involve the expenditure of a quite disproportionate amount of effort to achieve a very limited chemical goal, namely, the condensation of an amino-group with a carboxyl group to give a substituted amide. Inspection of the present two books should, however, convince such critics that the real position is quite otherwise, mainly owing to the presence in amino-acid side-chains of highly reactive functional groups and the large number of steps necessarily involved in the synthesis of even a relatively small peptide. The effort that has gone into the improvement of peptide syntheses in recent years has led to remarkable advances, and many peptides which it is now possible to synthesize comparatively easily would have presented almost insuperable difficulties a few years ago. The most noteworthy landmarks in this technical advance include the introduction of the *t*-butoxycarbonyl group for amino-group protection, of the *t*-butyl ester group for carboxyl protection, and of the mixed anhydride, carbodi-imide and *p*-nitrophenyl ester coupling methods.

There are signs of some slackening of pace in the development of new methods and the present time is very opportune for the appearance of an authoritative and comprehensive review of methods of peptide synthesis. The first volume of *The Peptides*, by Schröder and Lübke, is just such a review and is clearly destined to become the standard work on the subject. The authors are well known, active workers in the field and their mastery of, and feeling for, the subject are evident on every page of their book.

The first three chapters of the volume, which deal generally with amino- and carboxyl-group protection and with coupling methods, are perhaps the most valuable; the very many available methods are fully and critically discussed and there are clear indications which will be particularly useful to newcomers to the field of those methods which are of most general use. At the end of the second chapter there is a useful table showing the behaviour of the principal protecting groups towards a graded series of reagents. Chapter 4 is concerned with the application of these general methods to the synthesis of peptides of individual amino-acids, particularly those containing reactive side-chain functional groups; this chapter contains valuable tables listing the known synthetically useful derivatives of the more important trifunctional amino-acids. The volume ends with six short chapters on specialized topics, a very comprehensive list of literature references (well over 3,000) and good author and subject indexes. The literature coverage is claimed to be complete until nearly the end of 1964; in the main, this claim is justified although there are some surprising omissions. The translation is more than adequate and traces of the original German can only be detected here and there.

This book has been in almost daily use in my laboratory for the past six months. It has proved invaluable as a reference book, as a bibliographical source and as an aid in planning peptide syntheses and is now regarded as indispensable. The appearance of the second volume, which will deal with biologically active peptides, is awaited with great expectations. Every peptide chemist should have his own copy of this book and there should be one in every good chemical library. Unfortunately, the rather high price seems likely to restrict the book's circulation; perhaps, when a second edition is required, the price might be reduced by abandoning the policy of printing the full bibliography in both volumes.

Peptides, edited by Prof. Zervas, is in no sense a rival to, or substitute for Schröder and Lübke's book. It is more correctly described by its sub-title and contains most of the forty-six papers read at the Sixth European Symposium, held in Athens in September 1963, together with much of the discussion. Noteworthy omissions are the papers by Sieber and Schwyzer on the total synthesis of ACTH and that by Boissonnas on structure–activity relationships in analogues of the post-pituitary hormones, both of which have been published elsewhere. The majority of the papers deal with peptide synthesis although there are a few on the degradation and physical properties of peptides. The first European Peptide Symposium was held in Prague in September 1958 and the seventh is being held in Holland this September. Many new advances in peptide chemistry have been first announced at these meetings and there is no doubt that the free discussion and interchange of ideas at these meetings of a relatively small group of active workers have greatly helped progress in the field. However, the advance information given at these meetings ought not to be restricted to participants but should be made as widely available as possible. This calls for rapid publication and it is a great pity that no less than two and a half years have elapsed between the Athens meeting and the publication of these *Proceedings*, especially since the proceedings of the seventh Symposium held in Budapest in September 1964, were published (*Acta Chim. Acad. Sci. Hung.*, 44, No. 1–2) in August 1965. A real effort should be made to publish symposium proceedings more rapidly and in some less elaborate form, such as offset photolithography. It is probable that the

majority of the papers presented at the Athens meeting and collected in this volume have now appeared in full elsewhere; for this reason these *Proceedings* will be of much less general value than they might have been and may, indeed, only appeal to those who already possess the proceedings of the other meetings and wish to make their collections complete. H. N. RYDON

NEMATODA *et al.*

Traité de Zoologie

Anatomie, Systématique, Biologie. Publié sous la direction de Pierre-P. Grassé. Tome 4 (Deuxième Fascicule): Némathelminthes (Nématodes). Pp. 1–732. Tome 4 (Troisième Fascicule): Némethelminthes (Nématodes, Gordiacés), Rotifères, Gastrotriches, Kinorhynques. Pp. 733–1498. (Paris: Masson et Cie., 1965.) Br. 320 francs; Cart. 344 francs deux volumes.

Traité de Zoologie has already earned distinction and represents the conjoint efforts of many distinguished specialists. The first part of Volume 4 dealt with the Platyhelminthes, Mesozoa and Nemertini and the second and third parts extend the treatment of helminths. About five-sixths of these two large books is concerned with the Nematoda, one-sixth with the Gordiacea, Rotifera, Gastrotricha and Kinorhyncha, the rotifers taking up most of this remainder. The first half of the section on the Nematoda is devoted to structure, development, reproduction, ecology, host-parasite relationships and adaptations to the parasitic habit, the other half to systematics. Under the heading of "External Morphology" there is a wealth of information concerning form, size, colour, symmetry relations, cephalization, modifications of the two ends of the body, and the organization and arrangements of amphids and phasmids, the cuticle, spines, scales, tubercles, alae, bursae and suckers. The finer structure and composition of the cuticle come under the heading "Internal Morphology", along with the consideration of glands, musculature, the parenteric cavity, sense organs and nervous tissue, and accounts of the arrangements within the digestive, nervous, excretory and reproductive systems.

Development and reproduction next come under consideration. Embryonic development shows some homogeneity, notably in respect of rigorous cell lineage, and the first difference between species of nematodes concerns the form of the blastula and various modes of gastrulation. Segmentation and gastrulation are treated in some detail for *Parascaris equorum*, likewise the organization of the ovum and details of the first three divisions. The possibility of regulation in nematode development is considered, and various theories concerning the structure and development of the egg are discussed. Early stages of organogenesis are little known and are therefore treated briefly, but the influence of external factors is noted. The processes of growth, moulting and encystment are specially considered and information on organogenesis is supplemented by a discussion of the phylogenetic implications of this stage of development. Other matters which are treated and discussed include gametogenesis, fecundation, the structure of sperms and egg membranes, sexuality and intersexuality, the proportions of the sexes, hermaphroditism and pseudogamous species. Topics such as the epigenetic determination of sex, alternation of generations, polymorphism of heterogenic species and modes of reproduction are also discussed, as are the transmission of various characters and speciation in the Nematoda.

A short section on the ecology of free-living nematodes includes useful details of techniques for their investigation. This is followed by separate accounts of the parasites of invertebrates and vertebrates, and also plant-parasitic nematodes. Parasitologists will be specially interested at this point and in what follows, when the physiological peculiarities of nematodes are discussed in terms of their action on the hosts and considered as examples of Brumpt's five categories of action—spoliatory, toxic, traumatic, mechanical and irritative—although it is properly emphasized that the pathogenic effects of nematodes are usually complex. A brief statement on the principal symptoms of nematode infections of man and animals is followed by discussion of manifestations of immunity in vertebrate hosts. To conclude this part of the work there is a succinct account of the morphological adaptations of nematodes to parasitic modes of life.

The taxonomic scheme which is adopted includes subclasses, infra-classes, orders, sub-orders, super-families and families. The class Nematoda is divided into two sub-classes, Adenophorea (Aphasmidia) and Secernentea (Phasmidia). The two infra-classes of Adenophorea are the Chromadoria, with thirty-one families arranged in five orders (Araeolaimida, Monhysterida, Desmodorida, Chromadorida and Desmoscolecida) and the Enoplia, with about thirty-two families arranged in three orders (Enoplida, Dorylaimida and Enoplides). The sub-class Secernentea has about sixty-seven families arranged in five orders (Rhabditides, Tylenchides, Strongylida, Ascaridida and Spirurida). The entire class of nematodes is thus credited with about one hundred and thirty families arranged in thirteen orders. The great virtue of this scheme is that it is comprehensive, including free-living and plant-parasitic nematodes as well as the more familiar parasites of animals. Until fairly recently, parasitologists have been content with schemes which take only the parasitic nematodes of vertebrates into consideration, and, in 1961, Yamaguti arranged these forms in eleven orders and sixty-two families, although most of them are contained in three or four orders of this French scheme. Students and teachers alike become uneasy when major taxonomic schemes do not agree, and they may be dismayed by the great contrast between these two schemes. To discuss details is out of the question but, to make a point briefly, the order Strongylida (Strongylidea) contains eleven families in each of the two schemes, but six families in the French scheme (Amidostomatidae, Dictyocaulidae, Heligsomatidae, Metastrongylidae, Ollulanidae and Strongylacanthidae) are represented by subfamilies in Yamaguti's scheme, which contains six families (Cloacinidae, Cyathostomidae, Pharyngostrongylidae, Protostrongylidae, Pseudaliidae and Stephanuridae) that do not appear in the rival scheme. The order Spirurida (Spiruridea) contains sixteen families in each of the two schemes but Yamaguti's includes seven families (Ancyracanthidae, Haplonematidae, Rhabdochonidae, Rictulariidae, Sallobrellidae, Seuratidae and Skrjabinuridae) that are not included in the French scheme. The Tetrameridae is given the new name Tropisuridae, the Anguillicolidae and Dracunculidae are placed in the order Philometridea, and four families (Diplotriaenidae, Filariidae, Setariidae and Onchocercidae) are assigned by Yamaguti to the order Filaridea. The order Ascaridida (Ascaridideа) has sixteen families in the French scheme but only four in Yamaguti's, some families being placed in the order Oxyuridea. It is certain that much closer international co-operation will be required before finality is reached in the classification of the Nematoda and other classes of helminths. At present there is no consistency even in respect of word endings chosen to denote various taxons.

However, the high standard of the volumes of *Traité de Zoologie* has been maintained. Misprints are rare but some family names are not shown in the contents and, presumably because of the long period spent in the press, references to the original literature for the 1960's are very sparse. The exquisite line diagrams are notable, although more annotation is required in many of them. Perhaps this is the finest exposition of helminth structure which has yet appeared but more information might have been

given on the fine structure of the cuticle and other parts. Zoologists and parasitologists alike will be delighted by information and ideas here consolidated. Without the complete coverage here afforded any attempts to deal with the affinities of the Nemathelminthes (Aschelminthes) are futile. This topic is treated adequately, various theories are mentioned and the arguments of protagonists of the theory that the nematodes are derived from arthropods are stated fully but reasons are given for their derivation from Dalyellian Turbellaria. It is shown that the various classes considered have such affinities as merit their grouping as Aschelminthes and it is suggested that paedomorphosis (neoteny), which has sometimes been held to account for the relative simplicity of nematode structure, has played an important part in giving origin to the various groups. BEN DAWES

GRAFTS FOR MAN

Histocompatibility Testing

Report of a Conference and Workshop sponsored by the Division of Medical Sciences, National Academy of Sciences, National Research Council, 7–12 June, 1964. (Publication 1229.) Pp. 192. (Washington: National Academy of Sciences–National Research Council, 1965.) $6.00.

The Biology of Tissue Transplantation

By Paul S. Russell and Anthony P. Monaco. (New England Journal of Medicine Medical Progress Series.) Pp. viii+207. (Boston, Mass.: Little, Brown and Company, 1965.) $6.75.

IF the transplantation of tissues and organs between one human being and another is to become a routine surgical procedure, then the graft donor must be chosen so that he has as many antigens as possible in common with the prospective recipient and possesses as few antigens as possible which are absent in the recipient. To make such matching possible, methods must be sought to determine what antigens are present on human cells. *Histocompatibility Testing* is a testimony to the amount of research at present being done in this field and to the ingenuity of the workers concerned. The first part of the report is devoted to the results of the various contributors trying to "type" or antigenically analyse cells *in vivo* and *in vitro*. This section is so well summarized by H. Sherwood Lawrence that an attempt to do so in this review would be superfluous. The second part of the report is devoted to the description and practical details of the tests used to obtain the results presented earlier. Most authors have made a valuable contribution to this section, describing their tests in detail, together with possible pitfalls. There are, however, certain annoying deficiencies which could easily have been avoided. Some authors have sacrificed clarity for brevity; others do not always quote the exact concentrations of reagents; one author almost completely neglects to describe his test at all; yet another describes a standardization procedure which he certainly could not carry out himself (nor, it might be added, could anyone else). However, this book does provide, for those interested in tissue typing, a good progress report.

The Biology of Tissue Transplantation, by two surgeons who practise both applied and experimental tissue transplantation, represents an up-to-date review of the field of transplantation immunology. As such it is of interest both to the surgeon and to the experimental biologist and deserves to be read by both. The authors have presented both the old-established facts and present research trends in a readable form. The sections on the nature of the homograft reaction, the alteration of the immunological reactivity of the graft recipient, and the clinical aspects of transplantation are excellent. On the other hand, transplantation antigens deserved to be treated much more critically. The one general criticism of an otherwise excellent book is that the authors have been a little too prone on occasions to take at face value some of the claims made in the literature quoted. As some 600 references are cited, this is perhaps, to a certain extent, understandable. G. GOWLAND

REMARKABLE AND FEARSOME

Foundations of Anesthesiology

By Albert Faulconer and Thomas E. Keys. Vol. 1: Pp. 1+1–716. Vol. 2: Pp. 1+717–1337. (Springfield, Ill.: Charles C. Thomas, 1965.) $38.50.

ANAESTHESIA is one of the fastest growing fields of modern medicine. This is true not only of its technology, but of the understanding of the fundamental processes which it involves both at the level of the organ and at that of the cell. It is natural that amidst the welter of new knowledge, the origins of the old on which the new is built might be overlooked or even misunderstood. Sometimes the full implication of new observations is not realized through lack of care in reading the original accounts of earlier experiments, and much time and effort may thereby be needlessly wasted. Albert Faulconer, an anaesthesiologist in the Mayo Clinic, has joined forces with Thomas Keys, a librarian and historian particularly interested in anaesthesia, to gather together a large series of papers which they rightly consider to be the foundation stones of modern anaesthetic practice and understanding. Their volumes will both educate and make humble any anaesthetist who reads them and they will provide a long lasting source of information for any physician or biologist interested in this field. They make clear that while modern technology is of great importance in anaesthetic research, essentially intellectual processes of reasoning count for as much, and were particularly important when deductions were made from data which were often obtained with the simplest of equipment.

The 150 papers which are collected in these two volumes cover most of the wide range of the anaesthetic field. The majority would be difficult to find in the original, and many are translated into English for the first time.

Almost any page opened at random produces a gem. What better example than this quotation from Sir Humphry Davy in 1800, "Supposing that no part of the water evolved in solution by the expired gas of common air is formed immediately in respiration, it will follow that a very considerable quantity of oxygene must be constantly *combined* with the red particles, even allowing the consumption of a certain portion of it to form carbonic acid; for the carbonic acid evolved, rarely amounts to more than three fourths of the volume of the oxygene consumed", or this from Flourens in 1847, when ether was being increasingly used, mostly by completely unqualified people who regarded it as an innocuous substance: "When the surgeon contemplates the possibility of the use of ether in an operation, the prime consideration must also be borne in mind: ether which possesses the power to abolish pain can also endanger life. Hence the new agent which has just been added to the resources of surgery is at once remarkable and fearsome." This statement is as true to-day of the wide range of anaesthetic drugs now available as it was then of ether, and is the basic reason why anaesthesia has become such a highly developed specialty within the general field of medicine. Many of the papers in these volumes could be regarded as of historical importance only but others are of quite immediate importance.

These books will provide good reading, intellectual delight, and scientific education for as long as they are possessed, for their contents will never age.

W. W. MUSHIN

BRIDGING THE GAP

Neurohistochemistry

Edited by C. W. M. Adams. Pp. vii+753. (Amsterdam, London and New York: Elsevier Publishing Company, 1965.) 160*s*.

THE title of this book is slightly misleading as the contents cover a much wider field. Although the greater part has been written by the editor, there are ten other contributors. The work is divided into three sections, in which histochemistry is dealt with as a technique, in relation to the investigation of normal nervous tissue, and in connexion with neuropathology.

The editor's introduction emphasizes the importance of histochemistry in bridging the gap between conventional histology and the biochemistry of homogenized tissues. He appears to regard it as more closely orientated towards histology and thus as an extension of a staining technique. This is far too limited, for as Glenner points out in his chapter: "the potential of histochemistry is great for it offers an unexcelled opportunity to relate cellular and intracellular structure to physiologic function". Furthermore, most pathologists would hope that modern histochemistry might be able to reveal cellular abnormalities underlying "biochemical lesions" in tissues which are known to be functioning abnormally but in which no abnormality of structure can be detected by conventional histological methods.

The opening part of the book is devoted to histochemical methods and is not intended to be exhaustive. It thus gives a very useful introduction to the subject and an adequate bibliography is available for those who wish to delve deeper into the subject. In addition to histochemical methods, techniques for single-cell examination and autoradiography are included and future developments taken care of by a chapter on electron histochemistry by Torack, and all of this is very valuable. The distinction between histochemistry and cytochemistry is made very sharp chiefly because of the different methods of preparation. In the broader search for knowledge this distinction is artificial, for each technique makes its own contribution to the final composite picture of a pathological lesion. On the whole, this histochemical section is satisfactory, though there are a number of minor points which call for comment. For example, it is stated on page 11 that acetylation of Sudan black gives rise to "improved staining" though this is by no means certain; on page 85 Deitch[1] is credited with the introduction of 2-4-dichlorophenol in the Sakaguchi reaction, though this was recommended by McLeish *et al.* in 1957 (ref. 2). On page 88, glycogen is said to be bound to protein (desmoglycogen), yet Meyer and Jeanloz[3] proved that although it may be mechanically included in coagulated protein it is never chemically bound to it. On page 91, it is stated that there is uncertainty about the mechanism of metachromasia, although the physical chemistry of this subject has been worked out by Michaelis several years ago. Glenner deals very fully with enzyme histochemistry, and his discussions on factors affecting enzyme localization and characterization are most timely. Quantitative methods are discussed by Glenner and also by Davidson and Gregson in a later chapter on the cytochemistry of the nervous system. In the first section of the book there is a large amount of useful information on lipids and this embodies much work done by Prof. Adams and his colleagues.

The future of histochemistry is so closely bound up with pathology that the last section is particularly welcome. It is in many ways, perhaps not surprisingly, the most interesting part and the editor is able to convey his enthusiasm for the subject of myelin and the demyelinating diseases. So often in the past histochemistry has been dealt with as a subject on its own and often neglected by pathologists. The chief value of this work will be to encourage the neuropathologist to supplement conventional techniques with modern chemical methods, and the general background of histochemistry in the book will be sufficient to enable him to embark on a new discipline. For the painstaking production of this excellent work Prof. Adams is greatly to be congratulated, and he can feel assured that it will remain the standard work on this subject for many years to come. It may well result in the appearance of similar volumes on other specialized branches of pathology.

The production of the book is of high quality and attractive, and the illustrations of an equally high standard. Errors are few, though one mentions somewhat reluctantly that histochemistry is spelled "hystochemistry" on the page of contents. G. J. CUNNINGHAM

Space Travel and Exploration

By Harrie Massey. (A *Contemporary Physics* Reprint.) Pp. iv+117. (London: Taylor and Francis, Ltd., 1966.) 18*s*.; $2.60.

BETWEEN February 1964 and June 1965 Sir Harrie Massey contributed a series of articles on space research and exploration to the journal *Contemporary Physics*. These articles have now been collected and published as a paperback volume, with notes on some more recent developments. The book begins with a swift survey of the main uses of artificial satellites and space vehicles. Then comes discussion of "Ways and Means", covering the velocity requirements for space missions, the types of rocket, methods of tracking, and the design of solar cells. The third section gives some results of scientific studies of the Earth and its upper atmosphere, and the fourth section is concerned chiefly with the Sun's influence over the Earth's atmosphere. Section 5 begins with lunar and planetary probes, and then returns to the mundane applications of satellites in meteorology and communications. The next section has biology as its theme and, appropriately enough, splits neatly into two halves: (*a*) "can there be micro-organisms living in space or on planets?" and (*b*) "can we keep macro-organisms (especially *homo sapiens*) living happily in space?" Finally there are the notes on recent advances, up to late 1965.

No one has a better appreciation of space research in all its aspects than Sir Harrie Massey, and his book provides a clear and well-balanced review of the major developments up to 1965. Much of the detail had to be left out, of course, and readers who wish to pursue particular items in greater detail will find it difficult to trace the original papers, since no references are given. The book list at the end is not really adequate as a substitute and is indeed sometimes slightly capricious in its choices. Apart from this very slight imperfection, however, the book can be strongly recommended as a sound introduction to the present state of space research.

D. G. KING-HELE

Friction and Wear in Machinery

Edited by G. Herrmann. Translated from the Russian. Pp. x+334. (New York: The American Society of Mechanical Engineers: London: Pergamon Press, Ltd., 1960.) n.p.

THIS is a collection of papers on wear, friction and lubrication which describe work carried out at the Institute for the Science of Machines of the Academy of Sciences in Moscow. The papers were presented at a seminar there in 1955–56. The English translation, which is well done under the editorship of Dr. G. Herrmann, was made under the auspices of the American Society of Mechanical Engineers. Some fifteen papers are presented. The

preface to the Russian edition (1958) is written by Prof. M. M. Krushchov and the first four papers deal with his investigations with his colleagues of the wear of non-homogeneous materials including steel and cast iron. It includes the use of replica electron microscopy to examine the damage to the surfaces. The emphasis is on materials which are of engineering and practical importance. The second series of papers is by Prof. I. V. Kragel'skii and his associates on the friction of solids, the effect of surface roughness, relaxation oscillations in elastic friction systems and a useful practical paper on the development of high frictional composite materials which are valuable as brake materials. The rest of the papers deal with fluid lubrication, with the behaviour of dynamically loaded bearings and with the influence of temperature and of viscosity. Some experiments with a four-ball machine for testing lubricants are also described. At the end of the book there is an extensive and useful bibliography of relevant papers published both in Russia and elsewhere during the years 1954–55.

Because of the time which has elapsed since the papers were first written much of the work is necessarily now out of date, but the book can serve as a source of reference and it is interesting to see collected together this account of the able and effective work which the Russian scientists and engineers have been doing in this field.

F. P. BOWDEN

Gas Chromatography of Metal Chelates

By Ross W. Moshier and Robert E. Sievers. (International Series of Monographs in Analytical Chemistry, Vol. 23.) Pp. viii+163. (London and New York: Pergamon Press, Ltd., 1965.) 35*s*. net.

THIS book has been written for the mutual interest of both gas chromatographers and inorganic chemists and should prove of considerable value to both. Liberally supplied with references, it not only constitutes a comprehensive survey of the literature of metal chelate gas chromatography but also indicates several potential avenues for future investigation.

In discussing the general conditions required for successful gas–liquid chromatography of metal complexes, volatility and ease of formation are considered. Among the special complexes singled out are the metal acetylacetonates and their fluorocarbon derivatives. In the former case, their value is diminished by some lack of stability at the column temperatures required for gas–liquid chromatography. The greater volatility of the fluoro-derivatives (the most thoroughly studied of which are the tri- and hexa-fluoro compounds) makes possible separation at lower temperatures, which provides more suitable conditions for quantitative analysis. Thus for hexa-fluoro complexes, which can be eluted at little above room temperature, thermal degradation gives no cause for concern.

As a general indication of viability for gas–liquid chromatography, sublimation behaviour is discussed; for example, while the neodymium chelate with trifluoroacetyl acetone resists chromatography, the hexafluoro complex which can be sublimed slowly at 100° C/0·05 mm presents a more hopeful possibility.

After general considerations there follows a sufficiently comprehensive description of gas chromatographic technique, in the context of the compounds discussed, to initiate those unacquainted with this technique and to remind the esoteric of the special considerations which must be borne in mind when chromatographing these compounds. The relative merits of several applicable detectors is discussed. A chapter on "Analytical Determinations" deals with the practical problems of metal chelate preparation, extraction and chromatography. Useful detailed examples are included together with information on retention times. The authors conclude with a consideration of some of the applications of gas chromatography of the metal chelates, including the resolution of optical and geometrical isomers and its application to kinetic studies. An appendix of metal compounds of β-diketones is also included.

E. A. WALKER

Beiträge zur Biochemie und Physiologie von Naturstoffen

(Festschrift Kurt Mothes zum 65 Geburtstag.) Pp. 581. (Jena: Veb Gustav Fischer Verlag, 1965.) 105 MDN.; 179*s*. 2*d*.

THIS volume celebrates the sixty-fifth birthday anniversary of Kurt Mothes. It includes an introduction by Prof. A. Butenandt, followed by fifty articles on subjects concerned mostly with plant biochemistry, and particularly with the biosynthesis of plant constituents, including alkaloids. Fifteen of these articles are in English, one is in French, and the rest in German.

An article by Sir Robert Robinson entitled "Retrospect" surveys some of the author's many contributions to ideas and experiment in the field of plant biosynthesis, including the celebrated *in vitro* synthesis of tropinone. Prof. M. Florkin, of Liège, under the title "Paleoproteins", surveys briefly the evidence for the presence and nature of proteins in fossils, while the veteran Prof. K. Freudenberg writes about the biogenesis of lignins in a most interesting article.

The collection of essays in this volume emphasizes how successful in many instances has been the purely chemical approach to the problem of biosynthesis in plants. Although any generalization is dangerous, animal tissues, with their greater complexity and in general more rapidly effective synthetic processes, are firmly dependent on enzyme-catalysed and directed processes in a manner that does not hold so completely for plant tissues. Be that as it may, the subject of phytogenesis is one the lines of which were foreshadowed and elucidated by the methods of organic chemistry in a way that has not in general held for zoogenesis. And the contributions of organic chemistry to phytogenesis are widely and interestingly surveyed in this book.

F. G. YOUNG

The Thread of Life

An Introduction to Molecular Biology. By John C. Kendrew. (Based on the series of B.B.C. Television Lectures.) Pp. 110+52 photographs. (London: G. Bell and Sons, Ltd., 196€.) 21*s*. net.

THIS book sets out to tell the story of the "revolution in biology" represented by our new understanding of the relationship between molecular structure and biological function—in short, molecular biology. In the informal personal style preferred by television audiences (or, anyway, by producers) Dr. Kendrew outlines the way proteins are constructed, moves on to nucleic acids and the idea of coding, and ends with viruses. The last chapter speculates on how genes (operons) are switched on and off.

Needless to say, no one is better qualified for the task. The only doubts which rise concern the adaptation from a visual to a written medium. Though Dr. Kendrew writes "You can easily see . . .", the fifty-two photographs—excellent in themselves—are all placed at the end of the book. Since they are an essential part of the explanation, they should have been married with the text. Moreover, the density of information is pretty high: the whole story in 30,000 words. On paper, one might relax the pace a bit. The lectures were given early in 1964: so, though footnotes have been added to cover Holley's structure for RNA and Phillips's work on lysozyme, the publishing delay has made the story not fully up to date. In short, an opportunity to produce something exceptional missed through lack of publishing enterprise. Even so, Dr. Kendrew's lucid summary will be welcome to any layman who seriously wants to try to grasp this fascinating subject.

G. RATTRAY TAYLOR

MEETINGS

NEW STRUCTURAL METHODS

OXFORD—1966

A SYMPOSIUM on "Newer Physical Methods in Structural Chemistry" was held during July 18–21 in New College, Oxford. The meeting was somewhat out of the ordinary in that it was organized not by a scientific society but by the journal *Laboratory Practice*, and running alongside the conference a small and most useful exhibition of equipment relevant to the main themes had been arranged. The experiment was successful, and it is tempting to think that it would be welcome in other areas.

The meeting provided an opportunity, taken by more than 120 delegates, to catch up on and discuss recent developments in two areas—first, mass spectrometry and, then, optical rotatory dispersion and circular dichroism. These topics had been suggested by the president, Sir Robert Robinson, and he, together with Prof. Carl Djerassi and Prof. W. Klyne, had been largely responsible for indicating the direction that the symposium should take.

The thirty-one papers presented divided somewhat in favour of mass spectrometry (by 19 to 12). To some degree this division of interest was real, but Prof. Djerassi, who gave the first paper, has been a pioneer in both fields. He dealt with the migration of alkyl groups and oxygen functions in fragmentation processes. It was apparent in this, as in other papers, that the mapping of a fragmentation pattern requires extensive studies (accurate fragment masses, metastable peak observations, isotopic labelling) if a reasonably certain interpretation is to emerge. In this area some particularly elegant experiments involving labelling by both deuterium and carbon-13 were described by Dr. B. J. Millard (Liverpool). Dr. D. Williams (Cambridge) described many other examples of rearrangements, and the story was taken up by Prof. M. Fetizon (Paris) and Prof. A. Maccoll (University College, London), who discussed respectively the relation of fragmentation pattern to stereochemistry and the behaviour of ureas and thioureas on electron impact.

Computer techniques are popping up practically everywhere, and it was no surprise that when attention turned to rotatory dispersion, two contributors discussed the application of such techniques in the interpretation of optical rotatory dispersion curves of polypeptides and proteins. The Cotton effects of aromatic compounds are also attracting a good deal of attention. Prof. Klyne and Mr. R. J. Swan (Westfield College, London) presented some new results in this area and Dr. K. Kotera (Osaka) put forward a rule of the octant type to correlate his observations on a series of lycorine alkaloids and related compounds. But then Dr. G. Snatzke (Bonn) presented a different treatment, and it was evident that something of a controversy is in the making. In the open forum which followed, Prof. Djerassi emphasized the difficulties involved: since guesswork has a fifty per cent chance of predicting the sign of the Cotton effect of a given compound, an especially extensive range of examples is required before a "rule" can graduate to the status of a rule.

One of the most elegant papers in the second section was that given by Prof. S. F. Mason (East Anglia) on the non-empirical determination of absolute configuration using circular dichroism. Aromatic chromophores were again concerned, and the treatment based on coupled oscillators which has already been published for calycanthine was extended to several related compounds, to Tröger's base, and to diphenyl systems of the aporphine alkaloid series.

The conference was set at a cracking pace and although the open forum was a valuable session, longer breaks for discussion between papers—when points at issue were still fresh in the mind—would have been welcome.

R. BONNETT

MICROCIRCULATION METHODS

IN connexion with the fourth European Conference on Microcirculation recently held in Cambridge (June 26–July 2) a four-day symposium on methods suitable for use in the study of the microcirculation of the blood was organized by Prof. H. Wayland of the California Institute of Technology. The number of participants was restricted to twenty-seven so that workers with scientific, medical and engineering interests were brought closely into contact during a series of meetings and short specialized lectures.

During the past thirty years a great many disciplines have become involved in the study of the microcirculation but knowledge of the processes of flow and exchange which occur is fragmentary and largely qualitative. Most of the effort at the meetings was concentrated on techniques for measuring four microcirculatory parameters—microvascular geometry, exchange across the capillary wall, intracapillary pressure, and the velocity of blood and its components. The choice of ancillary equipment and methods of data processing was also discussed.

There was agreement at the meeting on the desirability of knowing the total geometry of the vascular pattern in each tissue and organ, the fluctuation with time of the distribution of blood, and the variations under physiological and specific pathological conditions. The quantitative description of the vascular pattern should include the number, length and diameter of each type of blood vessel and, if possible, the thickness and composition of the walls, the branching angles, the distance between branches and the presence or absence of specific peripheral networks. Data on the endothelial surface area for each type of blood vessel, the volume density of capillaries and the maximum diffusion distances were also required. Such information, which is not at present available, would permit better and more detailed correlation of structure with function and the construction of vascular models for analysis of variables. Dr. C. Piovella (Pavia, Italy), Prof. E. H. Bloch (Cleveland, U.S.A.), Dr. H. J. Berman (Boston, U.S.A.), Dr. W. Bolt (Cologne, Germany) and Dr. S. S. Sobin (Los Angeles, U.S.A.) divided the methods available for such studies into three categories; first come the '*in vivo*' techniques of angiography, microscopic visualization of the blood vessel at the surface of tissues and organs, and the introduction of optical fibres into the depths of a living tissue. The second category includes perfusion after death with a dye or a fluid medium that hardens into a cast, and the third the immediate capture of the living state for subsequent analysis by rapidly freezing the tissue or injecting silicone elastomers into the living preparation. In all cases, much patient and often tedious routine measurement will be needed in order to provide the required data. Two simple but potentially useful suggestions were, first, that investigators who work with a particular organ, tissue or membrane preparation should describe its vascular pattern in a quantitative and reproducible manner and, secondly, that a reference marker of a stated length (preferably placed initially in the optical path) should be incorporated into all figures and illustrations of the microvascular system.

Four methods of determining the exchange across the capillary wall were introduced by Prof. C. Weiderhielm (Seattle, U.S.A.), Prof. B. W. Zweifach (New York, U.S.A.), Prof. S. Witte (Erlangen, Germany), and Dr. G. Freytag (Hamburg, Germany). They are the video scanning of dye movement, the Landis technique for calculating fluid exchange, the visualization of the movement of plasma constituents by tagging with fluorescent dyes and the use of tritium-labelled material in autoradiographic studies. In summing up, Prof. A. Silberberg (Rehovoth, Israel) pointed out that deficiencies common to the first three are that data have so far been obtained solely on the circulation in the mesentery, and that no allowance is made in them for lymph drainage which undoubtedly is a significant factor in protein and water movement. The autoradiographic technique would appear to be most suitable for the analysis of the structural elements involved in the exchange process but a major disadvantage in the present state of development is its inability to yield quantitative information. It was emphasized that there is a strong possibility that even in a given tissue the phenomenon of exchange may not be uniform either in time or in different parts of the bed so that the problem of sampling is a major consideration.

The desire to measure the hydraulic forces existing in the microcirculation results primarily from the study of fluid exchange across vessel walls and the need to quantify flow in small vessels. Methods presently in use were discussed by Dr. J. W. Irwin (Boston, U.S.A.), Dr. M. Intaglietta (Los Angeles, U.S.A.), Prof. J. F. Merlen (Lille, France) and Dr. A. M. Benis (Cambridge). They can be divided into two types depending on whether or not the vessel wall is penetrated. In the non-puncture type the measurement is made by deforming part of the vessel wall and relating the force necessary for a given deformation to the transmural pressure existing in the vessel. An inflatable diaphragm applied against the vessel can also be used, when the pressure needed to stop flow in a given vessel is related to the internal pressure. Both methods are subject to uncertainty because tissue and vessel wall resistance may influence the values obtained and pneumatic techniques for compressing the nail bed, followed by stepwise pressure reduction and observation of the resulting flow changes, were considered worthy of further development. Other non-puncture methods which were suggested included the analysis of red cell movement during the occlusion of the capillary with a fine probe and the injection into the vessel either of elastic microspheres (when changes in shape could be followed) or of filled red cell ghosts acting as osmometers with pressure-sensitive optical properties. For pressure measurements requiring the vessel wall to be penetrated by a hollow probe, two types of gauge are at present in use. In the active gauge, the pressure in the probe reservoir is continually adjusted by a servo system to balance the pressure in the vessel. Tip diameters range from 1 to 5μ and because the method requires practically no flow through the probe a response can be obtained very rapidly. The passive system must be designed to operate from the energy obtainable from the fluid inside the vessel. The problem is the conversion of the fluid power to an electrical signal through the choice of a proper transducer system. It was felt that the absolute lower limit of the tip diameter was about 5μ although a lower size might be used if only average pressure values were needed. The passive gauge should be of most value in vessels larger than 30μ in diameter; the active system extends measurements to the 8–10μ level. One serious limitation to all the methods is that they can be used only for vessels near the surface of tissue.

At normal haematocrits it is very difficult to resolve individual cells at the centre of mammalian vessels with diameters greater than about 40μ so that the main attention is at present directed towards the measurement of red cell velocity in capillaries. The main reasons for making the measurement are that it can be used to calculate oxygen transport and also to deduce the velocity profile of the blood, thus providing a measure of the total volume flow through the vessel. In the limiting case where single cells completely fill the vessel lumen the red cell velocity probably gives a true measure of the total volume flow and in principle may also yield an average of the haematocrit of the blood traversing that vessel. A variety of techniques was introduced by Prof. P. C. Johnson (Pasadena, U.S.A.), Dr. P. A. G. Monro (Cambridge), Dr. M. Steinhausen (Heidelberg, Germany), Dr. H. Meiselman (Pasadena, U.S.A.), Dr. A. A. Palmer (Sydney, Australia) and Dr. H. W. Thomas (Reading). They included streak photographs, analysis of ciné film sequences, analysis of the frequency spectrum of the variation of light intensity as cells cross a slit, and flying spot techniques. Methods for measuring whole blood velocity such as thermal dilution and the installation of electromagnetic flow meters were considered but there would obviously be severe practical difficulties in adapting them to the small vessels of the microcirculation.

The large amount of information which correctly designed measuring heads can produce calls for proper methods of data handling. These, it was felt, should be part of the experiment as a whole and improvements in measuring techniques will demand more complex methods of analysis of the data, involving analogue or digital computers or both. In summarizing the discussions, Prof. M. G. Taylor (Sydney, Australia) and Dr. R. L. Whitmore (Nottingham) suggested that the former would seem to be the method of choice for relatively simple procedures where a machine of modest size would suffice and permit the data to be analysed quickly under the direct control of the experimenter. It was also felt that an analogue computer might provide an easier introduction to data processing methods than the immediate use of a digital machine. On the other hand, when large amounts of data required editing and adjustment before analysis, or the number of variables was beyond the capacity of an analogue computer, or complex statistical methods were to be applied, the digital computer was the correct choice. It was generally agreed that as much experimental data as possible should be recorded on magnetic tape but that the amount of analysis which should be carried out "on line" must inevitably depend on the type of experiment. Small digital computers of the *LINC* type have been successfully used in neurophysiological experiments and their use in microcirculation work should be explored.

The needs of the clinician in requiring more detailed and exact information on conditions in the microcirculation were not forgotten, and Dr. E. Davis (Jerusalem, Israel), Drs. S. and S. C. Bunnag (Bangkok, Thailand) and Dr. W. G. Frasher, jun. (Los Angeles, U.S.A.), took active parts in bringing these requirements to the attention of the meeting. It was felt that the ingenuity and resources of scientists and engineers should be exploited by the development of appropriate instruments for routine clinical use. This, however, is scarcely possible until more is known of the variables which are of clinical importance in the microcirculation.

There is no doubt that we are about to see the large-scale application of quantified measuring techniques to the study of the microcirculation. This will call not only for improvements in existing research methods but for the development or invention of equipment which can be satisfactorily used in the tiny vessels of the microcirculation. Automated methods of data recording and analysis will also need adapting to the same ends. The symposium was particularly valuable in pointing out the probable directions of progress in microcirculation research over the next few years, and Prof. Wayland deserves the thanks of all who were fortunate enough to be present, for his initiative in organizing the meeting.

R. L. WHITMORE

EVIDENCE FOR A TWO-WAY SIDEREAL ANISOTROPY IN THE CHARGED PRIMARY COSMIC RADIATION

By R. M. JACKLYN

Antarctic Division, Department of External Affairs, Melbourne, and Physics Department, University of Tasmania, Hobart

FOR several years now the sidereal daily variation of intensity of cosmic ray mesons at the Hobart underground laboratory has been closely investigated[1,2]. In common with earlier investigations of this kind the objective has been to obtain decisive evidence either for or against a maximum of intensity among the charged parent primary particles from some fixed direction in space. The most important observational problem has been the possibility that the annual observed daily variation of meson intensity in sidereal time may contain a large spurious component, due to seasonal modulation of the solar daily variation of intensity. Therefore it will be necessary to outline the problem here briefly and show how peculiarly relevant it is to the observations. However, it is because of the distinctive nature of the observations and of the spurious effect that might be expected that it has been possible to design an experiment which makes it possible to decide whether the observed sidereal daily variation is in the main genuine or spurious. The first results of this experiment are presented in this article and confirm the earlier indications that there is a genuine two-way sidereal anisotropy among the charged cosmic ray primaries.

Although the charged primaries in the energy range 10^{10}–10^{12} eV are thought to be on the average very nearly isotropic in the vicinity of the Earth's orbit, a solar anisotropy has been detected[3], the intensity maximum as observed from the Earth having a fixed direction relative to the Earth–Sun line. It produces an observed solar daily variation whose average amplitude may be as great as 0·5 per cent. It might seem that if a comparable sidereal anisotropy existed among the charged primaries it could also be detected by arranging cosmic ray data in sidereal time. Such analyses have indicated that if there is a genuine sidereal component in the observed daily variation the amplitude must be less than about 0·1 per cent. Consequently, if a sidereal component exists it must usually be superimposed on a much larger solar component of the daily variation. In the simplest case this observational difficulty is overcome by considering annual averages: a solar component of constant amplitude and phase would be completely averaged out if the data were arranged in sidereal time, say month by month, and summed over a complete year. Unfortunately, the solar component may vary considerably from time to time and in particular may exhibit seasonal modulations of amplitude and phase. To illustrate the serious difficulties of interpretation that follow from this, let us consider a solar diurnal variation on which is impressed an annual sinusoidal variation of amplitude. The unmodulated diurnal wave can be regarded as a carrier, of frequency one cycle per day or 365 cycles per year. Amplitude modulation of one cycle per year produces matching sideband components of frequency 364 cycles per year and 366 cycles per year. The latter is the sidereal frequency, there being 366 sidereal days in a complete year. It follows that if a solar daily variation with impressed annual modulation of amplitude is arranged in sidereal time and averaged over one year, we observe an annual daily variation in sidereal time that is a completely spurious sideband effect. The time of maximum, or phase, of this spurious sidereal daily variation depends on the month of the year when the solar daily variation has maximum amplitude[4,5]. Therefore, on our assumption that maximum amplitude occurs during a particular season of the year, the phase of the spurious annual sidereal effect observed in the northern hemisphere will differ by 12 h from that observed in the southern hemisphere. This 12 h phase shift should hold at least approximately in practice even if the seasonal modulation of the solar component is rather complex. We shall see how important it is to be aware of this problem of the spurious effect when interpreting the observational data, although the material presented here relates in the main to daily variations of intensity underground, where seasonal changes of the solar component that are thought to be due to contributions of atmospheric origin should be considerably smaller than they are above ground.

Late in 1957 two semi-cubical vertical counter telescopes were installed at a depth of 40 m.w.e. (metres water equivalent) underground near Hobart (42·9° S geographic)[6]. Continuous records have been obtained of the intensity of mesons, the mean counting rate being about 70,000 particles per h. (It has been calculated that more than 90 per cent of this counting rate is due to primary protons of energy greater than 50 GeV and that the primary energy of maximum response is about 100 GeV)[7]. The time of maximum of the annual mean daily variation in sidereal time that has been obtained each year from the pressure corrected data has remained within the limits 0500–0700 local sidereal time[2]. Seasonal modulation of the solar component of the daily variation observed at this site appeared to have fallen to a very low level in the later years, so that from this point of view there was reason to believe that the sidereal effect might be genuine. Therefore it was of interest to compare the Hobart underground results with observations from similar equipment at a similar location in the northern hemisphere. Data from two (and later, three) vertical semi-cubical telescopes located at a depth of 40 m.w.e. at Budapest (47·5° N geographic) were obtained from the World Data Centre *WDC* 2 for the complete years 1959 and 1961. Fig. 1 shows that over the period the times of maximum of the apparent sidereal effect at the two places differed by approximately 12 h, whether judged by the first harmonics of best fit to the intensity deviations, or the sum of the harmonics, since the first and second harmonics are in phase. We have seen that this is what one would expect from a spurious sidereal effect generated by seasonal modulation of the solar component—a 12 h phase difference at places in opposite hemispheres. However, it is worth noting at the outset that this conclusion is not in accord with the evidence that the effect was still present when seasonal modulation was low. More than this, two cosmic ray phenomena of a somewhat different character that have been reported in recent years support the view that the sidereal effects shown in Fig. 1 are genuine. It may be of interest to describe them briefly, before proceeding to the more recent experimental results from Hobart.

In an investigation of monthly average daily variations obtained from neutron monitors and counter telescopes in the northern hemisphere during 1954, a year of minimum solar activity, Conforto and Simpson[8] found that over a period of some 6 months, the time of maximum expressed in solar time was becoming progressively earlier at the rate of approximately 2 h each month, in

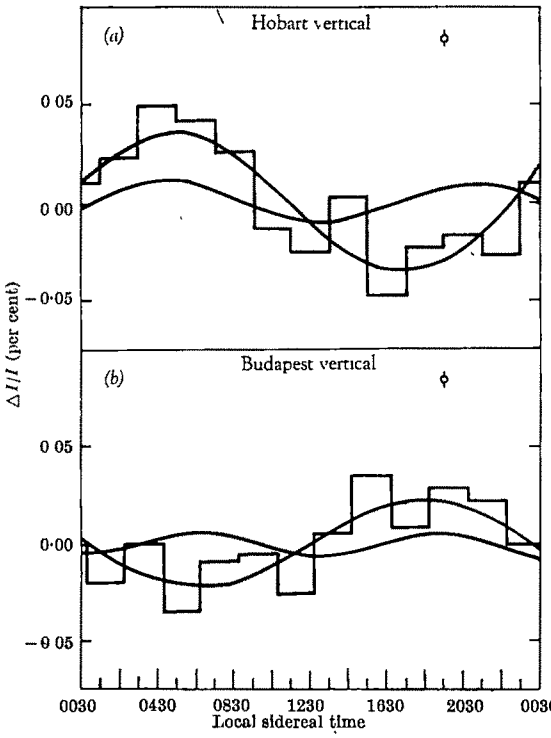

Fig. 1. The observed daily variation in sidereal time, averaged over the years 1959 and 1961, of pressure-corrected meson intensity from vertical semi-cubical telescopes at a depth of approximately 40 m.w.e. (*a*) At Hobart, scanning asymptotic latitudes in the vicinity of 39° S. geographic; (*b*) at Budapest, scanning asymptotic latitudes in the vicinity of 44° N. geographic. The error tails shown are the *S.E.*'s of amplitude associated with the first and second harmonics of best fit

the manner of a genuine sidereal daily variation with a maximum at approximately 2000 local sidereal time; however, it is most important to note that in their terminology this would be 0800 local sidereal time. As Baliga and Thambyahpillai[9] have pointed out, the authors had synchronized solar and sidereal time at the March equinox instead of the September equinox, the customary date, so that 12 h must be added to their published sidereal times of maximum to give the correct values. (This error also appears in a notable summary of the 1954 phase anomaly presented by Dorman[10]). The phenomenon was not detected in the southern hemisphere at that time, although the high counting rate data from the Hobart vertical meson telescope at sea level was carefully examined for the effect by Baliga and Thambyahpillai and by Parsons[11]. However, in 1961 a phase anomaly did occur at the Hobart underground site when the amplitude of the solar daily variation had reached a very low level, the maximum of the monthly mean daily variation in solar time becoming progressively earlier at the rate of 2 h each month, in the manner of a sidereal component with a maximum at 0700 local sidereal time. This time, so far as I am aware, the phenomenon was not detected in the northern hemisphere. In other words, it seems so far to have occurred in only one or the other hemisphere. This point will be reconsidered later. The event at Hobart has been described more fully in earlier publications[12]. Fig. 2 compares it with a typical example of the phase anomaly observed at northern latitudes in 1954, and we note the 12 h phase difference between the respective apparent sidereal maxima.

If, as it seems, the phase anomalies had been produced by genuine sidereal components of the daily variation, there would be no conflict of evidence with the annual apparent sidereal effects observed underground in 1959 and 1961 (Fig. 1) and with the longer term trends which indicated that the effect at the Hobart site was genuine. The inference would be that the direction of maximum intensity of the primaries observable in the northern sky differed from that observable in the southern sky by 180°, that is, a two-way sidereal effect exists. On the other hand, if the argument that the whole effect is spurious were to be sustained, the required seasonally modulated solar component of the daily variation would naturally have to be such as to resemble a genuine sidereal daily variation. To explain the phase anomalies, this would have to be a truly extraordinary seasonal phenomenon—a solar component, of constant amplitude, with a time of maximum which progressed anti-clockwise from noon in midwinter to midnight in midsummer. Nevertheless the evidence so far does not expressly forbid such a possibility.

What is now needed is a simple experimental result exhibiting the 12 h phase shift but explicitly ruling out an explanation based on seasonal changes of the solar daily variation. The first results from such an experiment are reported here.

In October, 1963, a narrow-angle telescope was installed at the Hobart underground site. It consisted of three standard metre-square trays in triple coincidence, the separation between the two extreme trays being approximately 10 ft., giving a total geometric aperture of 36°. The telescope was inclined at an angle of 70° to the north of zenith, so that the latitude of viewing along the axis was 27° N. geographic. Since the telescope responds in the main to primaries of rigidity greater than about 100 GV, deflexions of the trajectories of the primaries in the Earth's magnetic field would be no more than about 5°, so that one could be confident that the asymptotic cone of viewing was located in the northern hemisphere. On the other hand, the asymptotic cones of viewing for the vertical semi-cubes at the underground site are centred at about 39° S. geographic latitude and not more than about 15° E. of the meridian, depending somewhat on the nature of the primary phenomenon to which the telescopes are responding. It is concluded that the vertical and the narrow-angle inclined telescopes view within about 10° of each other in longitude when deflexions of the primary protons in the Earth's magnetic field are taken into account. The reader will now appreciate the purpose of this joint vertical-inclined experiment—to find out whether the apparent sidereal effect obtained from the inclined direction, scanning latitudes in the northern hemisphere, differs by about 12 h from the effect observed with the

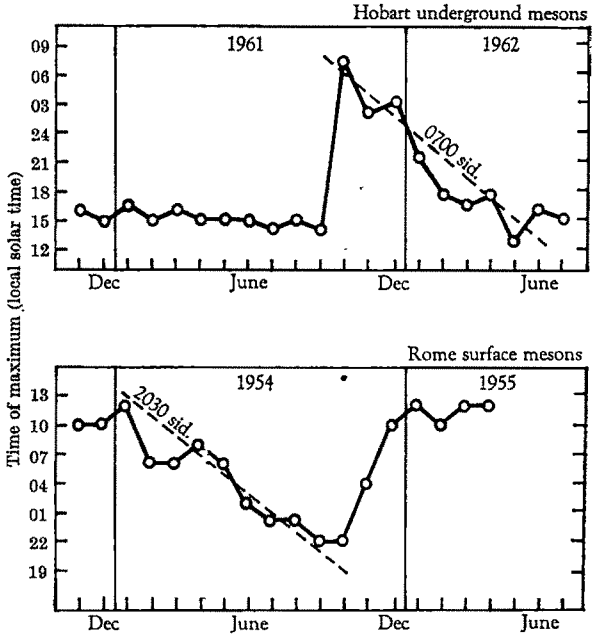

Fig. 2. Monthly averages of the time of maximum, in solar time, of the pressure-corrected daily variation of vertical meson intensity at the Hobart underground site (1961–1962) and at Rome (1954). The dashed lines represent the solar time equivalents of 0700 local sidereal time and 2030 local sidereal time as shown

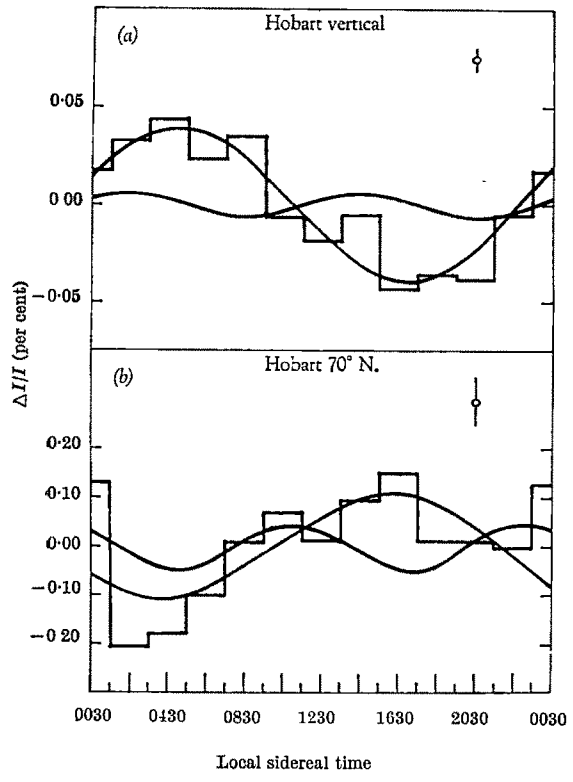

Fig. 3. The observed daily variation in sidereal time, averaged over the year 1964, of pressure-corrected meson intensity at a depth of approximately 40 m.w.e. at Hobart, (*a*) from two vertical semi-cubical telescopes, scanning asymptotic latitudes in the vicinity of 39° S. geographic, (*b*) from a narrow angle telescope inclined 70° to the north of zenith, scanning asymptotic latitudes in the vicinity of 20° N. geographic. The error tails shown are the *S.E.*'s of amplitude, associated with the first and second harmonics of best fit

vertical telescopes, scanning mid-southern latitudes. A 12-h phase difference could not be produced at the one place by any local (that is, atmospheric) process of seasonal modulation, usually thought to be responsible for spurious sidereal effects.

The histograms relating to the first year of operation, 1964, are shown in Fig. 3 with their first and second harmonics of best fit. It is evident that the sidereal daily variation in the vertical direction was much the same in 1964 as it was during 1959 and 1961. In the inclined direction the amplitude of the first harmonic is statistically significant at the 95 per cent level and the time of maximum differs by approximately 12 h from the vertical result. The respective times of maximum are in fact compatible with the Hobart–Budapest findings (Fig. 1) and with the values derived from the phase anomalies (Fig. 2).

We have seen that this latest result, while remaining to be confirmed over several years of observation, was the one to be expected from a sequence which as a whole indicated the existence of a two-way sidereal anisotropy in the primary radiation. The type of anisotropy is depicted schematically in Fig. 4. However, the second objective of the experiment was perhaps the most important one. It now seems scarcely possible that the sidereal effect could be spurious. (Elsewhere we shall also conclude this from considerations of the observed harmonics.)

It is of interest to note that the inward direction of the galactic magnetic field would be expected to pass overhead at about latitude 35° N. at 2000 local sidereal time, while the outward direction (looking towards the periphery of the spiral arm) would pass overhead at about latitude 35° S. at 0800 (ref. 13). These times roughly agree with the observed times of maximum of the sidereal effect. Corrections for deflexions of the primary trajectories in the Earth's magnetic field would improve the agreement. If it should happen that the galactic magnetic field is in fact the seat of adiabatic motions of the charged primaries

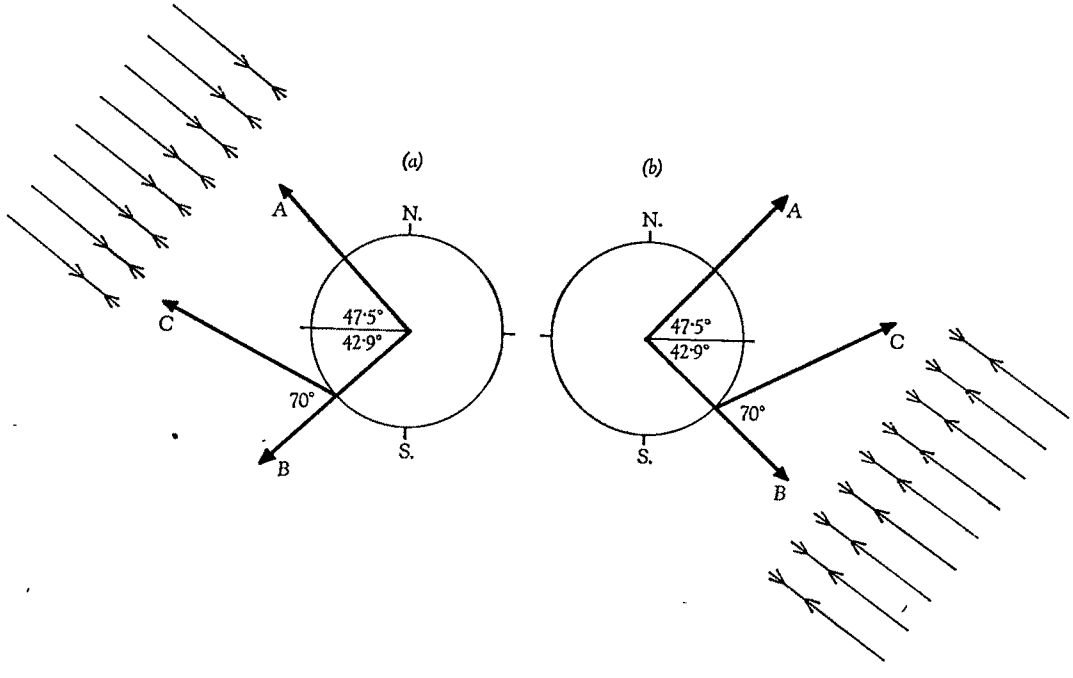

Fig. 4. Schematic diagrams showing the geographic headings of the vertical telescopes underground at Budapest (*A*) and the vertical (*B*) and inclined (*C*) telescopes underground at Hobart, (*a*) at the local sidereal time T h, (*b*) at the local sidereal time $T+12$ h. The parallel lines indicate primary intensity maxima both backwards and forwards along some fixed direction, having declination d, which passes locally overhead at the latitude d in the northern hemisphere at time T and at the same latitude in the southern hemisphere at time $T+12$

in both the backward and forward directions and that these are being detected as intensity maxima at the Earth, then the declination of the direction of the anisotropy should be that of the galactic field in the vicinity of the solar system. An estimate of the declination from cosmic ray intensity measurements will be presented elsewhere. It is based on a simple empirical model for the anisotropy and makes use of observations obtained in other directions in the plane of the meridian at the Hobart underground station.

It should be pointed out that in the model both the first and second harmonics of the sidereal daily variation have physical meaning. It is clear, for example, that at some latitude of viewing between Hobart and Budapest only a semi-diurnal effect should be observed, and that if the primary intensity maxima in opposite directions were equal, the first harmonic would disappear when the asymptotic cone of viewing was centred on the equator.

Finally, it is emphasized that although the first harmonic now being observed underground at Hobart is much larger than at Budapest (Fig. 1), this appears to be only temporary. Long-term trends of the apparent sidereal effect in the ion chamber data from Cheltenham (38·7° N. geographic) and Christchurch (43·5° S. geographic) indicate that the amplitudes were much larger in the northern than in the southern hemisphere during the early 1950's. This could be the main reason why a phase anomaly was detected only in the northern hemisphere in 1954 and only in the southern hemisphere in 1961. As to the changes in the relative amplitudes with time, the following suggestion is offered for what it is worth: when a sidereal effect is viewed through the region of interplanetary solar modulation, asymmetries in the modulating region with respect to the plane of the ecliptic might be responsible for different amplitudes in the northern and southern hemispheres. The amplitude differences would change from time to time as the asymmetry itself changed.

I thank Dr. P. G. Law, Prof. A. L. McAulay and his successor, Prof. G. R. A. Ellis, for their interest and support. I also thank especially Dr. A. G. Fenton, who has been closely associated with the project at all stages, for advice and discussions. I thank the Director of the Central Research Institute of Physics of the Hungarian Academy of Sciences (Cosmic Ray Department) for the underground cosmic ray data from Budapest, made available through the World Data Centre *WDC* 2.

SYMMETRY OF THE TIME AXIS

By Dr. F. R. STANNARD
University College, London

INTERACTIONS are governed by laws of physics that may be conveniently divided into two classes. Laws of the first type, such as those of energy and momentum conservation, must be rigorously obeyed in each interaction. These laws show no preferred direction of time, for reversal of the sign of t wherever it appears in the equations does not alter their validity. In the second class we have laws of a statistical character which dictate the probable outcome of many interactions considered as a whole. In this class we include the second law of thermodynamics and statements concerning the cross-sections for reactions. It is these laws which, while not distinguishing between any direction in three-dimensional space, nevertheless have an asymmetric behaviour with respect to the time axis. Thus, for example, the cross-section for a forward reaction in general differs from that of the reversed process. This is not because of any difference in the strengths of the two interactions, but arises as a result of the density of final states factors. Similarly, entropy is well known to vary in a systematic fashion with time.

Why the otherwise perfect symmetry of the space-time framework should be flawed by a restricted class of laws and in one dimension only has long been a subject of discussion. In this article I shall try a somewhat different approach to the problem. The question asked is: "If the time axis were perfectly symmetric in respect of *all* the laws of Nature, how would the world appear to us?"

The effect of imposing such a symmetry is best illustrated by taking a particular interaction as an example. Let us therefore consider the coupling between the neutron state and the $(p+e^-+\bar{\nu})$ state. The world lines of the particles involved in any such interaction may adopt the general configuration of Fig. 1 or Fig. 2. If the two time directions are indistinguishable there is no reason why either configuration should be favoured. Nevertheless, our observations do indicate a preference for one particular pattern of world lines, say those of Fig. 1, and these we refer to as representing the decay of a neutron, while Fig. 2 shows the creation of a neutron from a triple collision between a proton, electron and anti-neutrino. Once given such an asymmetric pattern of world lines, a direction in time can be defined, and laws formulated which describe the asymmetry in terms of the density of final states factors. Discussions on the symmetry properties of time generally do not seek to deny the existence of such laws and asymmetries, but centre rather on the nature of the contingency that allowed our world to choose between two equally possible sets of world line configurations.

The line of thought we are pursuing here is that no arbitrary choice has been made: both patterns of world lines are equally allowed at all times. This means that in addition to the neutron states with which we are familiar, there exist others such that the transitions from them to the $(p+e^-+\bar{\nu})$ states occur with the greater probability in the opposite direction of time, as in Fig. 2. So that we may distinguish between the two particle states, we introduce the concept of intrinsic time sense. Thus all particles besides carrying basic properties, such as mass, charge, isotopic spin, baryon number, and intrinsic parity, are also to be further sub-divided according to whether they have a positive or negative intrinsic time sense. So far as we know, all matter of which we have experience belongs only to one time sense category. Matter of the opposite time sense we shall designate as "faustian". Interactions between particles in faustian states would be identical in every respect to interactions between our own particles, except that their time asymmetry would be reversed.

Perhaps it should be emphasized that particles of a reversed time sense are not to be confused with particles moving backwards in time. This latter phrase is custom-

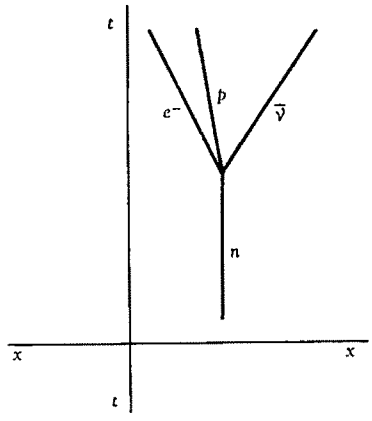

Fig. 1

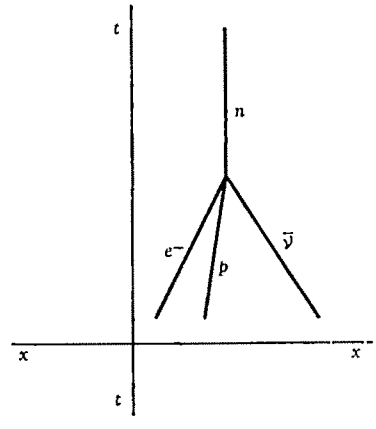

Fig. 2

arily reserved for equivalent anti-particles moving forward in time. As anti-particles obey the same dynamical laws as ordinary particles our proposal is for a further sub-division into particles of opposite time senses.

The question of whether we should be able to observe particles occupying faustian states clearly depends on the type of interaction to be expected between quanta of opposite time senses. There is in fact a strong probability that the two sets of particle states are independent of each other. This can readily be seen by imagining an experiment in which we observe interactions between a beam of our protons and a beam of faustian protons colliding with given energies and at a certain relative angle. There would certainly be some particles that would continue undeviated having failed to interact, and one might expect that the remainder would scatter through various angles with or without the production of other particles. Let us now perform the experiment in reverse. Beginning from a wide variety of states we would clearly find it difficult to produce, as a result of the interaction, only one final state, that is, the state originally regarded as the initial state. (This assumes, of course, that we do not artificially arrange the phases of the beams to cause destructive interference in all states except one.) The interaction as described therefore possesses an asymmetric behaviour with respect to the two directions of time. This is manifestly impossible for it was specified that we were dealing with particles of equal and opposite time sense. The overall time sense of the initial and final states is zero so there can be no way for the interaction to distinguish between the two time directions. There can in fact be no interaction.

In the case of non-corresponding particles, for example a beam of faustian electrons colliding with our protons, symmetry arguments tell us only that the time asymmetry of the interaction (if any) would be of the opposite sense to that of an interaction involving a beam of our electrons and faustian protons. It requires an additional assumption about the quantitative nature of the time sense before we can proceed further. If it is thought reasonable that all particles should have the same magnitude of time sense, in other words the significance is merely one of sign, we may now take as established that there would be no interaction between our matter and faustian matter. We shall discuss this assumption again later.

It would appear then that in a world that was perfectly symmetric with respect to the time axis, matter of opposite time senses would decouple. The faustian universe would be embedded in the same space-time framework, and yet would remain unobservable to us. According to our experience of time, the direction of which is dictated by the intrinsic time sense of the matter from which we are constructed, the faustian world would consist of galaxies absorbing their light rather than emitting it, living organisms growing younger, neutrons being created in triple collisions between protons, electrons and anti-neutrinos, and thereafter being absorbed in nuclei, etc. It would be a universe that was in a state of contraction, and its entropy would be decreasing, and yet the faustian observers would not be aware of anything strange in their environment. Being constructed of faustian matter their subjective experience of time is reversed, so they would be equally convinced that it was they who grew older and their entropy that increased. They would infer that it was our world that showed the unfamiliar behaviour. This rather odd situation, it will be recalled, has a close parallel in the special theory of relativity where two observers in relative motion are equally convinced that it is the other observer's clock that is going slowly.

Thus in a perfectly symmetric universe all observers would be aware of an apparent asymmetry in time, an asymmetry that was merely a measure of their ignorance of the other half of the universe. Perhaps one ought to conclude at this point. Having devised such a universe, however, one is tempted to venture a few speculations.

First we note that there appear to be some striking resemblances between the faustian world introduced here, and the "shadow universe" of Nishijima and Saffouri[1]. The latter was postulated in an attempt to save CP invariance in the long-lived $K^0 \rightarrow 2\pi$ decay experiment[2]. The mechanism invoked was that some K_1^0s became shadow K_1^0s by a CP conserving interaction, and at a later time reappeared to give the observed long-lived 2π decay. One undesirable feature of the theory was that, in order to prevent shadow K_1^0s decaying to two shadow pions, this interaction had to be arbitrarily suppressed. This assumption is not necessary, however, if one is thinking in terms of faustian K_1^0s. We, the observers, must scan the faustian K_1^0 world line according to our time direction, and this takes us away from the end that is coupled to the two-pion state with the greater probability. A faustian K_1^0 created in a time sense flip interaction would remain stable until it once again became one of our K_1^0s. A second difficulty encountered by the shadow universe hypothesis was that there had to be no strong interactions between the two universes so as to account for the non-observation of shadow particles in other experiments. Okun and Pomeranchuk[3] have pointed out that this would mean that shadow K_1^0s produced in the neutrino experiments would have been able to pass through the shielding and decay in copious numbers in the detectors. In fact the number of such decays was not abnormally high. The same criticism, however, cannot be levelled so readily at faustian K_1^0s. As we have seen, there can be a strong interaction between non-corresponding quanta. Furthermore, the existence of such an interaction involving states with particles of both time senses does not require that there should also be interactions linking a state of one time sense only to a state of mixed time sense. There is thus no reason to

expect that in collisions between our particles we should have produced faustian particles.

Recently, experiments have been performed in which the interference between the long-lived K^0 decay and the decay of K_1^0s regenerated by K_2^0 interactions has been studied[4]. A method of testing whether the faustian universe theory has any bearing on the K^0 decay problem is to repeat these investigations with K mesons created as $\bar{K}^0$s. If CP is violated the same results will be obtained as before; if our alternative is correct the sign of the interference will be reversed[5]. The evidence from the interference experiments so far performed is somewhat against our alternative, but it cannot be taken as definitive because it is strongly dependent on an assumption that had to be made regarding the K^0,$\bar{K}^0$ content of the beam used. A second prediction we can make is that the charged to neutral branching ratio of the long-lived $K^0 \rightarrow 2\pi$ decay should have the same value as that of the normal K_1^0 decay. Finally, from the observed ratio of the numbers of long-lived to short-lived K^0s decaying to two pions we calculate the lifetime of the former to be 4×10^{-8} sec, that is, it lies very close to that of the K_2^0.

It might be thought that to invoke a time sense flip for the K_1^0 was unreasonable because the temporary disappearance of other particles from our universe has not been observed. However, it must be noted that a particle experiencing a nuclear or electromagnetic interaction will in general be in a different energy state to that of the corresponding faustian particle situated in the same field. A time sense flip links particle states of equal energy so any significant difference in the energies of the states concerned will lead to a strong suppression of the transition. In effect, the interaction can occur only for free neutral particles. If it is further required that the two lifetimes of the neutral particle should have values lying in a range that makes them accessible to measurement, one is virtually reduced to considering only the K_1^0, Λ^0, and Ξ^0 particles.

If the Λ^0 particle undergoes a time sense flip, the free hyperon will contain both types of particle. Two mixed states will be formed each with its own characteristic lifetime. A bound Λ^0 in a hyperfragment, on the other hand, would be in the nuclear field of the surrounding nucleons and thus be prevented from converting to a faustian Λ^0. It will therefore have the lifetime characteristic of our pure single time-sense state rather than of either of the two mixtures. Because the lifetime of a pure faustian Λ^0 would be infinite if it were prevented from returning to our world, we require the lifetime of the bound Λ^0 to be less than that of either mixture. Dalitz and Rajasekharan[6] have made theoretical studies of the lifetimes of hyperfragments, taking into account the modification to the lifetime of the Λ^0 expected because of the existence of bound states for the decay proton and the effects of the Pauli exclusion principle and the stimulated non-mesonic decay modes. In the case of ${}_{\Lambda}H^3$, which is the system that lends itself most readily to this type of treatment as well as to experimental investigation, the observed lifetime is found to be only about half the theoretical value, and so far no explanation of the discrepancy has been forthcoming. If the experimental data on hyperfragments are used to determine the lifetime of our pure Λ^0, the behaviour of the long-lived free Λ^0 mixture can be predicted. In particular it is noted that if our pure Λ^0 has *exactly* one-half the lifetime of the short-lived free Λ^0, then the two free Λ^0 mixtures have equal lifetimes. For several years now the Λ^0 lifetime measurements[7] have been in disagreement. We remark that this does not necessarily arise from faulty experimentation, but instead may be an indication that the Λ^0 is a particle mixture with two lifetimes, almost but not quite degenerate. Depending on the fiducial criteria used, so experimenters will include varying proportions of long- and short-lived Λ^0s in their samples.

A somewhat similar confusion also exists for the Ξ^0 particle[8]. This, however, could be due to poor statistics and cannot be taken as evidence of a Ξ^0 particle mixture.

Earlier it was pointed out that the decoupling of the two halves of the universe was dependent on the assumption that non-corresponding quanta had no interaction, in the same way as there was no interaction between corresponding quanta. Should this not be the case, the possibility opens up that one might be able to establish contact with faustian cosmic systems. Observations of these systems would pose unusual problems for, as was pointed out earlier according to our time reckoning, they will absorb radiation from their surroundings, not emit it. They will therefore not give rise to images on photographic plates One could, however, systematically scan a region of the heavens with a telescope fitted with a small sensitive thermal device in its focal plane, and see if it suddenly starts radiating energy to a point in space.

Finally, we mention the interesting possibility that if some means exists for the transfer of matter between the faustian universe and ours, a perpetual state of mutual regeneration could be established.

MODEL OF THE HIGH-ENERGY PHASE OF SOLAR FLARES

By Prof. P. A. STURROCK
Institute for Plasma Research, Stanford University, Stanford, California

The solar flare is a highly complex phenomenon of considerable importance in solar physics and geophysics[1,2]. Most theoretical attempts at understanding flares have centred on the flash phase. It has recently been argued[3] that the flash phase may be interpreted as a resistive gravitational plasma instability[4] associated with an anomalous density gradient of chromospheric gas supported by a sheared magnetic field. This suggestion fits well with a proposed model of quiescent filaments[5] with which solar flares are known to be closely associated.

In pursuing this model, it seems that the "main" phase of a flare is the manifestation of a "tearing-mode" instability[6] which spreads across successive shells of the sheared magnetic field, releasing the excess magnetic energy and returning the field to a current-free state. This is indicated schematically in Fig. 1, and agrees well with the "rising mound" appearance of limb flares[7] and the "receding double-filament" appearance of disk flares[8].

Although this model goes a long way towards explaining the principal optical features of most flares, it does not explain the remarkable high energy phenomena which some flares exhibit: Type II and Type IV radio bursts[9], proton acceleration[10] and the ejection of plasma clouds

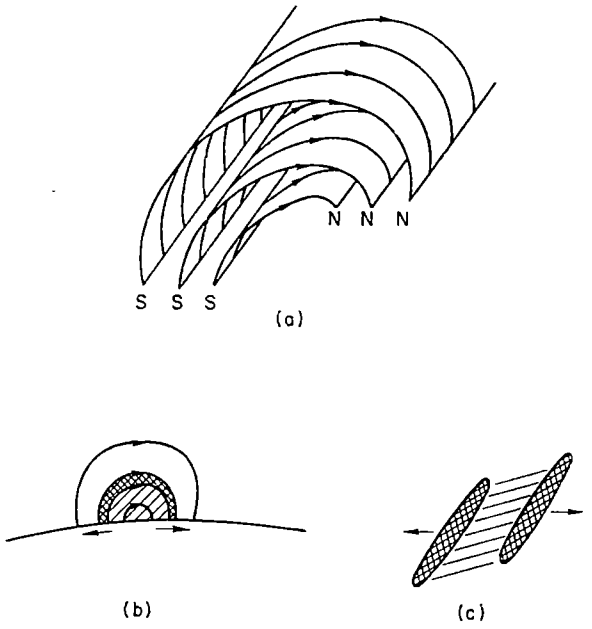

Fig. 1. *a*, Schematic representation of sheared magnetic-field pattern due to displaced line dipole. *b*, Limb view, and *c*, disk view of flare as it spreads across successive shells

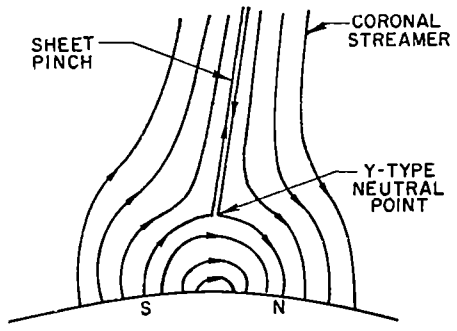

Fig. 2. Model of coronal streamer as bipolar flux tube formed from open-field configuration above closed-field region of bipolar field pattern

which may later produce a geomagnetic storm[11]. The purpose of this article is to offer a model which seems to account for this stage of solar flares.

The nature of coronal streamers[12] is of considerable significance for the flare phenomenon. For example, investigations of Type II and Type III radio bursts indicate that the exciters of these types of radiation move through regions of anomalously high density which are generally interpreted as being streamers[9]. Because Type III radio bursts are caused by clouds of electrons moving through the corona, and because these electrons must follow magnetic field lines, it follows that magnetic field lines run along the length of coronal streamers. Flares are normally produced by bipolar magnetic regions, and for this reason it is likely that the streamer contains flux of both polarity. This suggests that the relevant magnetic field configuration is that shown in Fig. 2, which is topologically identical with the "double-barrelled" tail of the Earth's magnetosphere[13] and can be termed a "bipolar flux tube". This interpretation of coronal streamers is supported by a recent coronal eclipse photograph taken by Dr. Sheldon Smith of the NASA Ames Research Center (to be published). It is to be noted that, as in the magnetosphere, there is a "*Y*-type neutral point" (or "line") which lies on the separatrix of the closed and open field lines, when it meets the "neutral sheet" or "sheet pinch" which runs the length of the coronal streamer.

The field configuration in the neighbourhood of the *Y*-type neutral point seems to be very sensitive to differences of plasma pressure between the closed-field region and the open-field region, having the form of an inverted "*T*" if the "external" gas pressure is the higher, and that of a cusp if the "internal" gas pressure is the higher. This property is probably responsible for the development of the bipolar flux tube from a closed bipolar field pattern. An excess of pressure in the closed field region will produce a cusp and then drive field lines out of the cusp along the sheet pinch, so augmenting the bipolar flux tube. When closed field lines are converted in this way to open field lines, gas "attached" to these field lines may escape into the solar wind, so that the gas pressure at coronal heights will drop, maintaining the pressure differential between closed and open field lines. If this is indeed the mechanism for the formation of bipolar flux tubes, the associated stored magnetic energy is derived from the non-thermal energy flux which heats the chromosphere and corona[14]. On an earlier occasion[15], it was noted that this energy flux is sufficient to explain the energy accumulated between homologous flares. (It is possible that the tail of the magnetosphere develops in a similar way, driven by the pressure of trapped high-energy particles in the radiation belts.)

Although, as is evident from the existence of the magnetospheric tail, the sheet pinch is metastable, it clearly represents a store of available energy which can be released by an appropriate instability. The relevant instability is generally regarded to be the tearing-mode instability[6], the steady-state non-linear stage of which has been analysed by Petschek[16]. Petschek's analysis indicates that the non-linear stage proceeds more rapidly than the linear stage, which implies that the tearing-mode instability is "explosive"[17]. If this instability is indeed explosive, this model offers ready explanations of the high-energy phenomena associated with solar flares.

When the tearing-mode instability (that is, the flare) extends into the open-field region, beyond the *Y* type neutral point, it will give rise to a reconnexion of magnetic field lines, as indicated in Fig. 3. The lower parts of the reconnected field lines will continue the process indicated in Figs. 1*b* and 1*c*. The upper parts of the U-shaped field

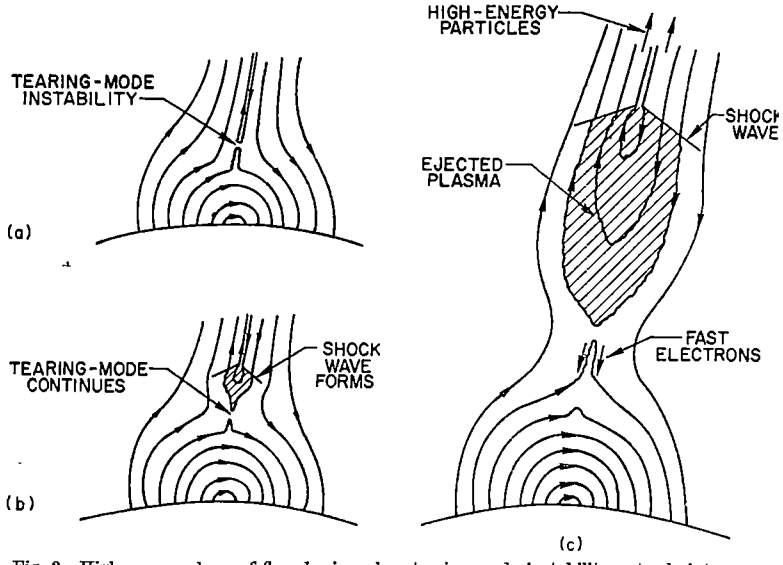

Fig. 3. High-energy phase of flare begins when tearing-mode instability extends into open-field region. (*a*), (*b*) and (*c*) are successive stages in formation of detached pocket of heated plasma and high-energy particles and its shock-wave interface with "pre-flare" coronal gas

lines now exert a tension on the plasma associated with it, so that this plasma will be ejected from the Sun as from a slingshot. Possible values of the area and magnetic field strength of a coronal streamer are 10^{20} cm^2 and $10^{1.5}$ gauss. Since the "scale height" of the field pattern would be comparable with the solar radius $10^{10.8}$ cm, the stored magnetic energy which would be released by the tearing-mode instability amounts to $10^{32.4}$ ergs. If the number density of the electrons and protons at the base the of streamer is taken as 10^{10} cm^{-3} and the density scale height as $10^{8.5}$ cm, the mass which will be ejected is $10^{14.7}$ g. If this mass were ejected into free space, it would acquire a velocity of 10^9 cm sec^{-1}, but this would be reduced by the interaction of the ejected gas with the pre-existing solar wind. Indeed, as Parker[11] has pointed out, the asymptotic form of the blast wave will be almost independent of the form of energy release. This estimate of the energy release is comparable with Parker's estimate of the energy release necessary to explain an intense geomagnetic storm.

The tearing-mode instability leads to the development of strong electric fields which, by a stochastic process[18], will accelerate both electrons and protons. Calculation of the rate of acceleration and final spectrum is a formidable problem, but some simplified calculations[19,20] have been made which corroborate the reality of the process. Electrons which, after acceleration, are caught in closed field lines will stream towards the surface of the Sun. If these electrons are deflected by the magnetic-mirror mechanism, the bulk of their synchrotron radiation will originate at the reflexion points: this offers an explanation of microwave Type IV radio bursts[9]. If at some height there is a favourable relationship between plasma and gyro-frequencies, the same two-stream instability may occur that has been observed by Waniek, Swanson and Grannan[21] and others, which gives rise to intense highly directional circularly polarized radiation. This would seem to explain stationary Type IV*m* radio bursts[9]. Electrons which, after acceleration, are in the "open" magnetic field configuration are likely to remain trapped in the moving "pocket" containing turbulent plasma and magnetic field. Synchrotron radiation by these electrons would comprise a moving Type IV*m* radio burst[9]. Accelerated protons in the closed-field region may go unnoticed, except for producing X-rays at the photosphere, but high-energy protons in the open-field region will leave the Sun and constitute "solar cosmic rays".

As the "magnetic pocket" is ejected from the surface of the Sun it moves into a region of lower magnetic pressure and lower gas pressure, and for this reason it is likely to expand transversely. It will also lengthen, partly due to the heating associated with the tearing instability and partly because the pocket is collecting coronal gas which is shock heated. Because the velocity of the ejected gas will be approximately the Alfvén velocity, the shock will move at a higher velocity. In consequence, a (collisionless) magnetohydrodynamic shock wave will trail from the "leading edge" such a shock wave, moving at just such a speed, is necessary to explain Type II solar radio bursts. These radio bursts are excited by kilovolt electrons accelerated in this shock front, just as electrons are observed to be accelerated in the Earth's bow shock[22].

It is clear that this model involves a number of complex plasma processes, each of which calls for lengthy detailed calculation. While such calculation is essential to confirm the model now proposed, the qualitative and gross quantitative agreements between this model and various high-energy phenomena of solar flares seem sufficiently striking to justify this preliminary publication.

A MODEL OF QUASI-STELLAR RADIO SOURCES

By Prof. P. A. STURROCK
Institute for Plasma Research, Stanford University, Stanford, California

The nature of quasi-stellar objects[1], originally identified by association with strong radio sources, remains an open question. It was remarked earlier[2] that the explosions which occur in quasi-stellar objects and those which occur in radio galaxies are similar not only to each other, but also to solar flares[3]. The proposal that the explosions of galaxies and of quasars, leading to radio clouds, could be interpreted as "galactic flares" could not at that time be developed in more detail because the mechanism of solar flares was not adequately understood. The model for the high-energy phase of solar flares, described in the preceding article[4], now makes it possible to construct a more detailed model of quasi-stellar objects.

One may argue very simply in favour of the explosions being flares. Ultra-relativistic electrons must have been accelerated by an electric field. A sudden spontaneous conversion of energy from one form to another is an instability. The kind of instability which generates electrical fields is a plasma instability. If there is to be more acceleration than heating, the gas density must be low. As a consequence, the energy released by the instability will be mainly magnetic. This is precisely what is generally believed to happen in the main and high-energy phases of solar flares.

Hoyle and Fowler[5] have argued that the energy released in some galactic explosions is so great (10^{59} ergs or more) that it is probably derived from the nuclear and gravitational energy of a compact body of gas of mass $10^5 M_\odot$–$10^8 M_\odot$ and small size, generically related to the nucleus of a Seyfert galaxy. If the mass is supporte

by gas and radiation pressure, it is prone to instabilities, including some of a relativistic nature[6], but these do not necessarily release energy of the required magnitude[7]. Moreover, a non-electromagnetic model cannot, of itself, yield particle acceleration.

These difficulties are overcome if it is assumed that the mass is supported principally by magnetic stresses. The stored magnetic energy will then be comparable with the gravitational binding energy so that the model contains enough energy in such a form that it can readily be converted into high-energy particles. The assumption that the magnetic field is closed presents certain difficulties, not the least of which is that of explaining the origin of the field. The assumption that the magnetic field is open circumvents these difficulties. The magnetic field must now be assumed to be primeval.

The nucleus of a quasar is in this model coupled magnetically to inter-galactic space. If there is a sharp drop in density at the surface of the central mass, there will be a field reversal, constituting a "sheet pinch", at the "ecliptic plane" of the system, as shown in Fig. 1. The sheet pinch will terminate in a circular Y-type neutral line outside which there will be a ring-shaped trap for accreting gas. The field lines coupled directly to the nucleus constitute a pair of "funnels" for accreting gas. Photographic evidence that such rings and funnels actually occur is provided by plates 143, 146 and other plates of Arp's *Atlas of Peculiar Galaxies*[8]. It is now tempting to re-interpret the observed gas flux of both *M*82[9] and *NGC* 1275[10] as accretion rather than explosion. (Dr. George Field has independently suggested, in private conversation, that the gas flux of *M*82 may be an influx.)

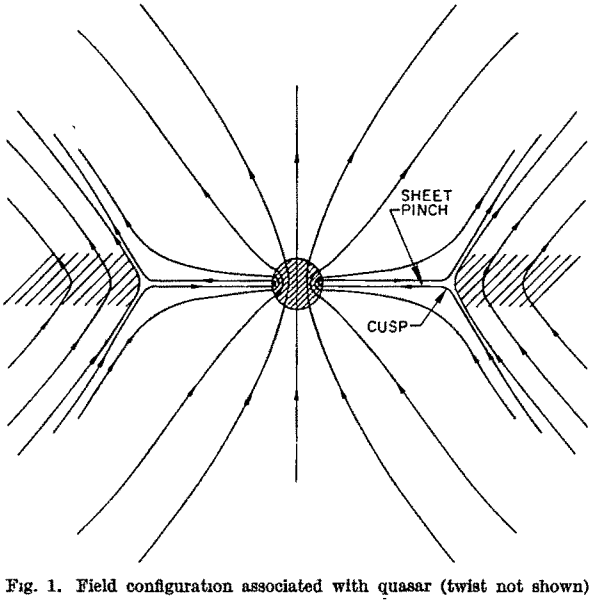

Fig. 1. Field configuration associated with quasar (twist not shown)

On balancing the magnetic energy and gravitational binding energy of a simple model, not too far from spherical[2], a mass-magnetic-flux relation is obtained of the form:

$$\Phi \approx 10^{-3} M \qquad (1)$$

where Φ is in gauss cm^2, M in grams, and the exact coefficient depends on the geometry. It is noteworthy that a typical sample of radio clouds, discussed by Maltby, Matthews and Moffet[11], are calculated to have fluxes in the range 10^{34}–10^{38} gauss cm^2, in excellent agreement with equation (1) and the Hoyle–Fowler hypothesis[5] that the explosions originate in galactic nuclei, for which $10^4\ M_\odot$–$10^8\ M_\odot$ is a reasonable mass range.

It appears that a magnetic field can offer only gross neutral stability. However, magnetohydrodynamic turbulence has an effective γ of 3/2 and so can provide gross stability. For a certain simple model, one finds that the oscillation frequency for radial pulsations ω may be related to the mean density ρ, the radius R and the Schwarzschild radius $R_s(= 2GMc^{-2})$ by:

$$\omega^2 \approx \pi G\rho\,(A^2 - 0{\cdot}55\,[R_s/R]) \qquad (2)$$

where A is the Alfvén number, that is, the ratio of the turbulent velocity v_t to the Alfvén velocity $v_A[= B(4\pi\rho)^{-\frac{1}{2}}]$.

The above and related equations make it possible to estimate parameters for the nucleus of the quasar 3*C* 273, if we interpret the observed 13 year periodicity[12] as a radial pulsation and the dispersion in gas velocity of "half-width" $10^{8\cdot3}$ cm sec^{-1}, inferred from emission line widths[13], as the turbulent velocity v_t. With the choice $A = 10^{-1}$, we then obtain $M = 10^{42\cdot3}$ g $= 10^9\ M_\odot$, $R = 10^{16\cdot2}$ cm (= 5 light days), $\rho = 10^{7\cdot1}$ g cm^{-3}, $\Phi = 10^{39\cdot3}$ gauss cm^2, $B = 10^{6\cdot4}$ gauss, $v_A = 10^{9\cdot3}$ cm sec^{-1}. The escape velocity is approximately v_A.

As was observed earlier[2], the likelihood of anomalous density gradients provides for the occurrence of flare flashes[14], which may explain the observed flashes in both optical and radio emission. It is also possible that magnetohydrodynamic instabilities may occur which could produce sudden changes in radius, either increasing or decreasing the optical luminosity.

We may now seek, in the present model, the analogue of the high-energy phase of solar flares described in the preceding article. The site for this phenomenon will be the sheet pinch which lies in the "ecliptic plane", and the mechanism will be the tearing-mode instability. The result will be a "pocket" of turbulent magnetic field containing high-energy particles being ejected by the tension of the magnetic field, as indicated in Fig. 2. If this occurs over only a small range of longitude, it will constitute a jet, and it is proposed that the jet of 3*C* 273 and the jet of *M* 87 (ref. 15) are manifestations of this mechanism. The fact that the synchrotron radiation of the jet of 3*C* 273 is detectable optically but not in the radio wave-lengths indicates that the spectrum is somewhat flat, implying that acceleration is in progress.

The hypothesis that radiation from the jet of 3*C* 273 is the result of continuing acceleration enables one to estimate the strength of the magnetic field at the tip of the jet. The rate of emission is about $10^{44\cdot3}$ ergs sec^{-1} and the cross-sectional area of the jet is about $10^{43\cdot9}$ cm^2. We make a conservative estimate of the field strength by assuming that the shock front at the tip of the jet is relativistic, advancing at the speed of light. On equating the rate of radiation to the rate of "dissolution" of magnetic energy, one obtains the estimate $B = 10^{5\cdot6}$ gauss at the

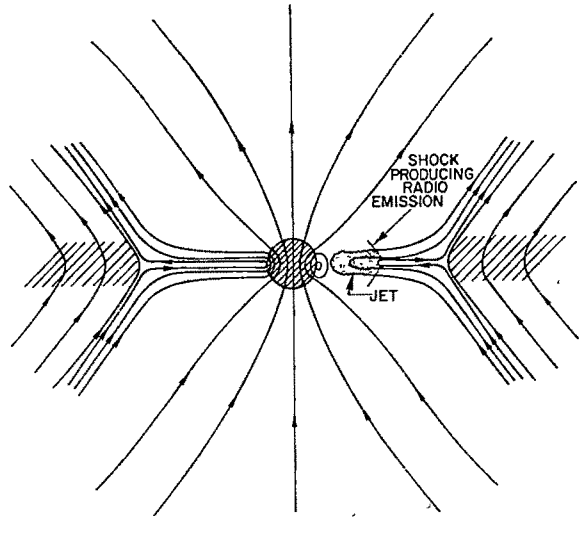

Fig. 2. Field configuration associated with quasar following flare, leading to jet formation

tip of the jet. Because the tip of the jet is at least $10^{23\cdot2}$ cm from the nucleus, the magnetic flux through each hemisphere amounts to $10^{42\cdot8}$ gauss cm^2. If we now refer to the mass-magnetic-flux relation, we see that this magnetic flux must be associated with a mass of $10^{45\cdot8}$ g, that is, $10^{12\cdot5}\ M_\odot$. Our model will not permit the visible nucleus *3C 273B* to have so great a mass. We are therefore led to the conclusion that surrounding the visible object *3C 273* is a much larger mass of gas which is invisible, presumably because it is fully ionized. We may note with some satisfaction that the presence of a mass of this magnitude will make it possible for the quasar to evolve into a galaxy as massive as *M87*, or conceivably into a cluster of galaxies.

It is interesting to enquire further into the likely fate of the jet of *3C 273*. It will continue as a jet until it arrives at the ring-shaped neutral line. At this point, the supply of magnetic energy will cease, and there will be no further acceleration. The cloud of electrons and ions, which have relativistic energies, will now divide into two clouds, about equal in size, one moving "northwards" and the other "southwards". This is indicated in Fig. 3. It is notable that a single explosion eventually produces two similar radio clouds at equal distances from the nucleus. In the case of *3C 273*, the nucleus will not be on the centre line of the double radio source when it forms (although it may seem so to other observers). However if, as seems quite possible, the flare were to extend over all longitudes, the end result would be two "smoke ring" radio clouds diametrically opposite with respect to the nucleus. We see that this model offers a simple explanation of the most striking characteristic of radio galaxies—their double structure.

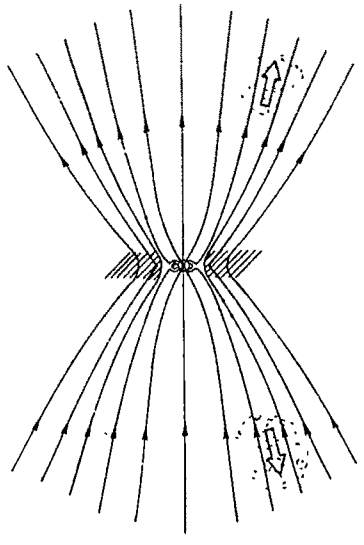

Fig. 3. Later stage, showing division of jet into two radio clouds (twist and effect of twist not shown)

Two possible interpretations of the radio source *3C 273A* present themselves. One is that the electrons responsible for the radio emission have been accelerated in a shock front at the tip of the jet . . . the same mechanism as is responsible for a Type II solar radio burst, although the electron energies would be greater so that we are seeing synchrotron radiation rather than radiation from plasma oscillations. The other alternative is that the jet has just arrived at the cusp so that we are seeing radiation from the first batch of electrons to move out of the acceleration region of the sheet pinch.

As was noted earlier, the funnelling action of the magnetic field has the result that intergalactic gas streams directly into the nucleus. Although the Jeans criterion is open to criticism[16], it will be used to provide an estimate of the radius of the sphere of intergalactic gas which has condensed to form the quasar. If in the formula $R_c = a(4\pi\ G\rho_0)^{-\frac{1}{2}}$, where a is the speed of sound and ρ_0 the density, we adopt the current estimate[17] $\rho_0 \approx 10^{-28}$ g cm^{-3}, we find the required temperature to be $T_0 = 19^{6\cdot2}$ °K; this may seem high, but it has recently been shown that the density of neutral hydrogen in intergalactic space is exceedingly low[18]. The corresponding value of R_c is $10^{24\cdot4}$ cm (800 kiloparsecs). This estimate enables us to calculate the intensity of the primeval magnetic field. As the flux of $10^{42\cdot8}$ gauss cm^2 originally threaded a sphere of radius $10^{24\cdot4}$ cm, the primeval magnetic field is of intensity $10^{7\cdot5}$ gauss. The primeval magnetic pressure was therefore comparable with the gas pressure. However, as Chandrasekhar[19] has noted, this would not have inhibited the gravitational condensation.

It was noted previously that the funnelling action of the magnetic field permits a high accretion rate leading to rapid evolution of the quasar. If we identify the optical radiation from the nucleus of *3C 273*, 10^{46} ergs sec^{-1}, as being due to accretion, the gas influx will be $10^{27\cdot2}$ g sec^{-1} or more, so that the evolution time (the time for the nucleus to double its mass) is 10^{15} sec ($10^{7\cdot5}$ y) or less. The inequality quoted in the previous sentence is based on the expectation that the inflowing gas will give up the bulk of its energy at a shock front (or series of shock fronts) at which the temperature is likely to be much higher than that of the visible surface of the nucleus. If the shock reheats the gas to a temperature comparable with the original (intergalactic) temperature, the radiation would be primarily in the X-ray band so that the X-ray output from the nucleus of *3C 273* may well exceed the visible radiation.

The main "galactic" mass of gas should also be a source of X-rays. Whether or not it is more intense than the X-rays originating near the nucleus depends on the size of the galactic mass (and weakly on its temperature). If the temperature is about 10^6 °K, X-ray emission from the galactic mass will exceed 10^{46} ergs sec^{-1} if the radius of the mass is less than $10^{21\cdot9}$ cm, that is, 2·5 kpc.

The present model suggests answers to many questions concerning quasars. In addition to those already mentioned, it is possible to explain why the formation of a small heavy object has not been inhibited by angular momentum: the 'open" magnetic field configuration provides a mechanism for retaining a low angular velocity during condensation by transferring angular momentum from the inner regions to the outer regions. One may also note that, with the high magnetic field quoted, the inverse Compton effect will be negligible in comparison with synchrotron radiation, so avoiding a difficulty which has led Hoyle, Burbidge and Sargent[20] to suggest that quasars are not at cosmological distances. Further, one may note that the explosion mechanism suggested for quasars will be applicable also to radio galaxies, if one assumes that the magnetic field of the nucleus of such a galaxy is similar to that which we associate with a quasar. Such a galaxy would indeed evolve from each quasar, according to the present model.

This chain of thought now offers an explanation of the recent remarkable observations of Byram, Chubb and Friedman[21], that certain radio galaxies emit X-rays at a power 10–100 times greater than the combined optical and radio output. This X-ray emission may be ascribed to an influx of intergalactic gas into the nucleus.

In view of the high magnetic field strength of the nucleus of *3C 273* (which is expected to be typical of quasars), the great mass of plasma surrounding the nucleus, and the various plasma phenomena which may arise, analysis of the radiation (including radio emission) from the nucleus appears a complex problem. One will need to bear in mind the possibility of proton synchrotron radiation and also of coherent radiation processes, as has recently been suggested by Ginzburg and Ozernoy[22].

Finally, we may suspect from the fact that solar flares produce high-energy protons ("solar cosmic rays") of

energies ($\sim$ 1 beV) much greater than that of electrons responsible for the radio emission (a few meV), that galactic flares should accelerate some ions to energies which are much greater than the energy of electrons in, say, the jet of 3*C* 273. The jet must contain electrons with energies of about $10^{12\cdot3}$ eV in order to give optical radiation in a magnetic field of strength $10^{5\cdot6}$ gauss. These electrons are decelerated by synchrotron radiation at a rate 10^6 eV sec^{-1}. Thus the stochastic acceleration process[23], which arises from the electric-field spectrum produced by the instability, has a maximum acceleration rate of at least this value. Protons are subject to the same acceleration, without experiencing significant deceleration. Any protons which have been accelerated at the maximum rate for the life-time of the jet (which must be at least $10^{12\cdot4}$ sec, as its length is 10^{23} cm) will have attained an energy of at least $10^{18\cdot5}$ eV. Multiply charged ions may have achieved a greater energy. Thus, it is possible that galactic flares are responsible for the high-energy component of cosmic rays.

THERMOSPHERIC ENERGETICS AND A POSSIBLE EXPLANATION OF SOME OBSERVATIONS OF GEOMAGNETIC DISTURBANCES AND RADIO AURORAE

By DR. REGINALD E. NEWELL
Department of Meteorology, Massachusetts Institute of Technology

ONE approach to the study of large scale atmospheric circulations pursued extensively during the past few years has been the examination of the atmospheric budgets of angular momentum, energy and mass. One asks how the transfer of zonal angular momentum into the regions with westerly winds and out of the regions with easterly winds is accomplished, how heat energy is transferred from regions of surplus to regions of deficit, and how water vapour is transported from regions where evaporation greatly exceeds precipitation to regions where the opposite occurs. The answers to such questions based on the observations now available have led us to picture the atmosphere as a series of superposed and interconnected heat engines and refrigerators. Investigations have concentrated on the following seven items: (*a*) meridional cross-sections of the zonal wind component; (*b*) the horizontal transport of angular momentum towards the poles, proportional to the covariance between the zonal and meridional wind components; (*c*) meridional cross-sections of temperature; (*d*) the horizontal transport of heat energy towards the poles, proportional to the covariance between the meridional wind component and the temperature; (*e*) meridional cross-sections of radiative heating and cooling rates; (*f*) meridional cross-sections of the distribution of trace substances; (*g*) the horizontal transport of trace substances towards the poles, proportional to the covariance between the meridional wind component and the concentration of the trace substances.

For the region of the atmosphere below 30 km items (*a*)–(*g*) can be obtained from the balloon sounding network data. No systematic experimental survey of item (*e*) has been conducted although estimates are available based on items (*c*) and (*f*). For the 30–65 km region, meteorological rocket network data have provided limited information about items (*a*)–(*c*), and the rocket grenade experiment has extended items (*a*) and (*c*) to about 80 km. Items (*d*) and (*g*) are not known. Item (*e*) is computed with fairly strong assumptions made about item (*f*), itself not yet properly measured. Nevertheless, the broad outline of the momentum and energy budget of the region below 80 km has been synthesized[1–5]. In the heat engine regions, radiative processes produce a meridional temperature gradient and the large-scale quasi-horizontal motions carry heat down this gradient. In the refrigerator regions the large-scale motions produce a temperature gradient, essentially through their vertical components, and radiative processes act to reduce this gradient; the motions themselves are forced by energy received from the heat engines. The same line of reasoning is applied here to the thermosphere above 80 km with particular emphasis on some geophysical consequences which have emerged.

The Thermosphere

Item (*a*) has been obtained from the tracks of meteor trails, ionospheric discontinuities, falling spheres and chemical clouds. Large scale circulation systems, small-scale waves and tides all influence the results. Fedor[6] and Murgatroyd[7] have made use of the ionospheric drift results with tides eliminated to extend zonal wind meridional cross-sections to about 120 km. Item (*b*) has been estimated from meteor trail data by Jones[8] and from ionospheric drift data[5]; tidal motions apparently play a significant part in the momentum budget. Item (*c*) has been derived from (*a*) by Murgatroyd[7] by means of the thermal wind equation and there is good agreement with the overall pattern as derived from falling sphere experiments. Whereas high middle latitudes at 80 km are warm in winter and cold in summer, they are cold in winter and warm in summer at 120 km. Items (*d*) and (*g*) cannot be derived from present observations. Mahoney

and Lagos[9,10] have recently presented computations of item (*e*), based on heating which results from absorption of ultra-violet and extreme ultra-violet radiation, conduction and infra-red emission by atomic oxygen. Their results show that the large-scale motions must transfer heat down the temperature gradient in the lower thermosphere in the direction of the poles at the equinoxes and towards the winter pole over most of the region at the solstices. Item (*f*) is available for the bottomside ionosphere from surface ionospheric stations and for the topside from *Alouette*, but only for electron concentrations.

Combining items (*c*) and (*e*), it is noted that diabatic heating occurs where the air is warm and cooling where it is cold, thus zonal available potential energy is generated. This energy is the maximum amount of total potential energy available for conversion into kinetic energy under any adiabatic redistribution of mass. The concept was introduced into meteorology by Lorenz[11] and has been extensively discussed by him and by Van Mieghem[12]. The situation in the 100–150 km layer is somewhat similar to that in the 30–50 km region. Some of this energy drives the motions which transfer heat towards the poles to balance the energy budget. These motions will have both zonal and meridional components and it has been argued elsewhere[5,9] that they are quite adequate to explain the difference in amplitude and phase between models of the thermospheric temperature distribution and deductions based on satellite drag. The lower thermosphere thus functions essentially like a heat engine. Is this surmounted by a refrigerator as is the case for the heat engines of the 0–10 km and 30–50 km layers? If so, the motions involved would be driven from the heat engine and there would be a tendency at the equinoxes for parcels moving toward the poles to subside and thus become warm and for parcels moving towards the equator to rise and cool. In fact, at the solstices one would anticipate a warm winter pole and a cold summer pole at heights of about 400 km if the temperature changes arising from the vertical components of the motion can offset the changes due to diabatic effects. Jacchia[13] has analysed the drag from a high-latitude perigee satellite which shows such a temperature distribution at 500 km although he feels there is an alternative explanation of the finding[14]. Thus, temperatures may increase with latitude at such altitudes in the winter and at the equinoxes. Such an increase has also been postulated from the composition measurements of the topside ionosphere[15,16].

Energy Calculations

A summary of the various atmospheric regions is presented in Fig. 1. The arrows represent possible interchanges of energy and will be discussed more fully later. In Table 1 there is a summary of the mean values for summer and winter of zonal available potential energy, its generation by adiabatic processes and the kinetic energy content of the 0–30 km region. The heating rates and temperatures used in these calculations have been presented elsewhere[17]. The equations used were those of Lorenz[11]. The tabulated values refer to atmospheric layers 5 km thick and bounded by latitudes 5° and 75° N. In each, temperature, wind and heating rates were read from cross-sections drawn for winter and summer at intervals of 10° in latitude. It is difficult to choose appropriate values for the troposphere, and considerable generation in the lowest 5 km has probably been omitted by the technique. Generation rates for the troposphere as a whole[3] are probably close to 2,000 ergs cm^{-2} sec^{-1}. Some 100 ergs cm^{-2} sec^{-1} leaks upwards out of the troposphere and is used to drive the lower stratosphere. About the same amount of energy is consumed in the tropical troposphere refrigerator and this is provided by lateral

transfer from the middle latitude troposphere. The middle stratospheric heat engine generates its own energy, about 20 ergs cm^{-1} sec^{-1}, in winter and in summer generates a smaller amount and probably receives energy laterally from the winter hemisphere. In addition, there is a possible flux of several ergs cm^{-2} sec^{-1} into the stratospheric heat engine from below in winter[18]. About 1 erg cm^{-2} sec^{-1} has to be supplied upwards from the heat engine in the 25–50 km region to the refrigerator in the 60–80 km region in winter and somewhat less than this in summer. Table 2 presents similar estimates for the 80–120 km region based on the radiative heating rates of Mahoney and Lagos[9,10] and a temperature distribution modified from Murgatroyd[7]. The generation rates in this region vary during the day by large amounts and are presented for four times. The same temperature structure was used for each time and a single wind structure for K_z. The results in Table 2 give a typical generation rate of about 20×10^{-5} ergs cm^{-2} sec^{-1} per 5 km thick layer for the heat engine region above about 105 km. A typical content of zonal available potential energy is about 10 ergs cm^{-2} and the ratio A_z/G_z is about 14 h. This time is so short, as I emphasized earlier[5], that much of the kinetic energy derived from the available potential energy probably appears in short-period motions, namely, the tides. It is also noteworthy that above 100 km in winter the kinetic energy content is larger than that of zonal available potential energy, as occurs in the 25–60 km heat engine but not in the troposphere. Some of the mean kinetic energy evident in the lower thermosphere may be derived from tidal kinetic energy. In turn the tidal kinetic energy may be partly derived from differential heating *in situ* and partly from tidal forces acting on the atmosphere below[19].

No doubt these numbers will have to be revised as more is learned about the upper atmosphere, but they do provide a guide to further exploration. They show immediately, for example, that the effects of the lower on the upper atmosphere are liable to be much greater than the converse effects. A similar conclusion has emerged from purely theoretical studies[20]. Although this may seem a trivial point, it is often ignored by investigators studying solar–terrestrial relationships.

Implications for K_p and Aurorae

The thermosphere is characterized by a number of temperature changes. Two of these which are well marked are the diurnal temperature change and the 27 day temperature change, and these are thought to be due to changes in the incident extreme ultra-violet radiation. In fact, the 27-day cycle has been demonstrated experimentally by Bourdeau *et al.*[21], who monitored solar extreme ultra-violet from a satellite for 2 months and compared the results with thermospheric temperatures derived from satellite drag data. A preferred area of extreme ultra-violet emission on the Sun produced higher thermospheric temperatures when directed towards the Earth. In so far as solar radio noise is also related to extreme ultra-violet emission and varies over the solar sunspot cycle, it has been argued by Nicolet[22] and others that the change in thermospheric temperatures that occurs over the sunspot cycle also results basically from changes in solar extreme ultra-violet emission.

The additional hypothesis will be made here that changes in the thermospheric temperatures and wind structure can be brought about by absorption of energy supplied from below. The hypothesis is not new and has been discussed in various forms by several authors[23,24]. With its aid it may be possible to account for the increases in thermospheric temperature associated with large values of K_p, particularly noticeable at high latitudes[25], and the increase in the drift speed of ionospheric irregularities also associated with large K_p (ref. 26). K_p itself is a global measure of the degree of disturbance of the Earth's magnetic field as monitored at the Earth's surface[27]. The normal quiet day variation of the surface magnetic field is thought to arise from electrical currents in the E-region. These in turn are apparently driven by the large-scale atmospheric motions. Because the gyro-frequency for electrons becomes equal to the collision frequency with neutral constituents at about 90 km while the same criterion for positive ions is not reached until about 140 km, there is a layer in the E-region in which ions are strongly influenced by atmospheric motions while electrons are strongly influenced by the Earth's magnetic field[28]; it is thus possible for the atmospheric motions to produce differential motions of the electrons and ions, in other terms an electric current. The current is manifested as changes in the magnetic field at the Earth's surface. When the field departs strongly from its regular variation it seems reasonable to assume that the E-region currents are responsible. Thus changes in either atmospheric motions or conductivity are the ultimate cause for changes in K_p. There seems to be no difficulty in supplying the perturbation magnetic energy from the kinetic energy; for example, a field change of 200γ corresponds to a change in magnetic energy of $\sim 2 \times 10^{-7}$ ergs cm^{-3}. whereas a typical kinetic energy density at 120 km, for a speed of 50 m sec^{-1}, is 5×10^{-4} ergs cm^{-3}.

Many attempts to explain auroral phenomena on the basis of charged particle streams from the Sun do not appear to be correct now that the solar wind has turned out to contain only relatively low-energy particles. A search is therefore under way for acceleration mechanisms that can act on terrestrial ions. The details are not yet clear; in fact, the relationships between motions of neutral particles, motions of ions, pressure gradients, electrodynamic forces and viscosity are not as yet completely understood[29–33]. The possibility that the charged particle energy comes ultimately from the kinetic energy of large-scale motions is one which has only been investigated in a preliminary fashion[34]. Seasonal changes in preferred L shells[35,36] and indeed their very existence may be related to preferred regions of atmospheric acceleration. Further work may use considerations such as those applied to the solar atmosphere by Starr and Gilman[37] with diffusion of magnetic field lines included. Nevertheless, it is clear that the necessary energy is readily available. The energy deposited in a typical aurora is about 10^{17} ergs sec^{-1} or 0·02 ergs cm^{-2} sec^{-1} when averaged over the globe, which is a relatively small fraction of the atmospheric energy available (see Table 1). Even a large event only involves 0·2 ergs cm^{-2} sec^{-1} compared with 100 ergs cm^{-2} sec^{-1} which is constantly being supplied by the troposphere to the lower stratosphere. It should be noted that the generation rates for the thermosphere alone are much too small to provide the energy (Table 2).

Students of the ionosphere are aware of the long debate 25–30 years ago between Hulburt, Chapman and others concerning the ultimate cause of geomagnetic disturbances. The principal mechanisms proposed were extreme ultra-violet and solar corpuscular radiation; the debate is delightfully summarized in the book by Chapman and Bartels[38]. The present hypothesis is that two factors can alter the circulation of the thermosphere and thereby produce geomagnetic changes; these are extreme ultra-violet changes (with concomitant conductivity and motion changes) and energy received from below. A particularly difficult problem is to differentiate between cases involving one factor alone, or both jointly. As an example, suppose that the energy transmitted from below is most effective (because the transmission of the lower thermosphere is high) when the extreme ultra-violet flux is at a minimum in its 27-day cycle or at a particular level below the maximum. Then geomagnetic disturbances (as opposed to regular variations) might predominate. This simple suggestion may suffice to account for the claimed existence of M-regions on the Sun. These "magnetically effective regions", so named by Bartels[38], were

introduced to explain the origin of magnetically disturbed conditions on the Earth which were not accompanied by visible solar disturbances.

Changes in the horizontal pressure gradient forces in the thermosphere which can be brought about as a response to changes in the thermal structure below could change the kinetic energy in the lower thermosphere. It is supposed here that this action occurs by way of the large-scale wave motions of the atmosphere below 100 km. The energy is supposed transmitted by pressure-work boundary terms rather than by an actual vertical flux of kinetic energy. The formal mathematical development applicable to vertical transmission by atmospheric motions of both large- and small-scale waves has been summarized by Van Mieghem[39].

Several years ago, Charney and Drazin[20] posed the question, "Why doesn't the Earth's atmosphere have a corona ?". They answered it with a preliminary numerical computation of the transmission of the atmosphere below 100 km to planetary scale, zero frequency, wave energy, which showed that in general such energy was trapped in the lower layers. Strong westerly winds or easterly winds in the 50–60 km region were found to inhibit the vertical flux of energy; only near the equinoxes when the winds were very light westerly could transmission occur. It is quite likely that small amounts of energy can escape at other times also and, in fact, it appears that the atmosphere does have a semi-permanent corona as shown by the presence of radio aurora. Equinoctial peaks in K_p and radio aurora[40] could thus result from an increased vertical energy flux at these times. They do not appear on the same dates each year and it is evident that the dates of optimum transmission of the atmosphere below 100 km are likewise variable. Other variables are the vertical energy flux from troposphere to lower stratosphere and the generation of energy in the 25–50 km layer.

As is common to most postulates concerning geomagnetic disturbances, there are several items that do not easily fit into the scheme. For example, the frequent suddenness of onset of a geomagnetic perturbation is difficult to explain. When long records of the circulation of the lowest 100 km are available it may be possible to distinguish characteristics associated with sudden and gradual disturbances. Another objection that might be raised is that K_p was found to be related to the solar wind velocity by the *Mariner* probe experiment[41]. It is difficult to argue that the changes induced in the magnetosphere could have produced changes in direction of the solar wind at such large distances. Nevertheless, there are no energy difficulties with the postulate and it may well be invoked for those radio aurora and K_p events not obviously related to events on the Sun. A similar postulate is often used to account for the temperature of the Sun's corona although usually the small-scale motions are held responsible; large-scale photospheric motions provide an equally attractive energy source.

A final comment concerning solar–weather relationships is that most investigators have examined meteorological processes occurring after K_p changes (with the assumption that K_p reflected a solar change). It may be more profitable to examine meteorological processes in the lowest 100 km before K_p changes.

It is clear that the hypothesis presented here can be tested when extensive observations of items (*a*)–(*g*) in the 80–300 km region have been collected so that their variations with time of day, season, position in 27-day and sunspot cycle and change with K_p can be assessed. If the hypothesis is correct, then such observations would have obvious practical applications.

Much of the research on which these comments are based has been supported by the U.S. Atomic Energy Commission. My colleagues, Dr. J. R. Mahoney and Mr. C. P. Lagos, kindly allowed me to see their heating rate computations in advance of publication. I thank Mr. M. L. Stone, of the M.I.T. Lincoln Laboratory, whose questions prompted this article.

THE REVERSIBLE OXYGEN ELECTRODE

By JAMES P. HOARE

Research Laboratories, General Motors Corporation, Warren, Michigan

FOR an electrode process consisting of a series of consecutive steps to be truly reversible, not only must the overall electrode reaction be the same in both the anodic and cathodic directions, but also each individual step of the forward process must be reversed in the back reaction. When oxygen is reduced at a platinum cathode in oxygen-saturated acid solution, hydrogen peroxide is detected[1,2] in the electrolyte, but when oxygen is evolved

at such an anode, hydrogen peroxide is not detected[3]. This observation indicates that the mechanism for the reduction is different from that for the evolution of oxygen at a platinum electrode, as hydrogen peroxide is a stable intermediate in the one case but not in the other.

On the basis of steady state polarization curves, Hoar[4] was the first to show that the extrapolated Tafel lines for the cathodic reduction and the anodic evolution of oxygen cross at the theoretically calculated potential value of 1·23 V (ref. 5). These data have been confirmed[1,2] and support the conclusion that the overall electrode reaction is the same for platinum/oxygen anodes and cathodes. The electrode process is the four-electron oxygen/water reaction:

$$O_2 + 4H^+ + 4e \rightleftharpoons 2H_2O \quad (1)$$

In the anodic evolution of oxygen, it is generally agreed that the first step is the discharge of adsorbed water molecules to form adsorbed hydroxyl radicals:

$$(H_2O)_{ads} \rightarrow (OH)_{ads} + H^+ + e \quad (2)$$

What happens next is not clear, because steady state polarization measurements give information only about the rate-determining step which appears to be equation 2 (refs. 1 and 2). Probably a method using short pulses may yield evidence of the nature of the steps which follow the rate-determining step. However, a possible path which seems reasonable is as follows. The hydroxyl radicals may interact, producing an adsorbed oxygen atom and a water molecule:

$$2(OH)_{ads} \rightarrow O_{ads} + (H_2O)_{ads} \quad (3)$$

Finally, two adsorbed oxygen atoms may combine to form the adsorbed molecule of oxygen from which oxygen is desorbed:

$$2\,O_{ads} \rightarrow (O_2)_{ads} \quad (4)$$

The current goes into the formation of hydroxyl radicals, but oxygen is evolved from the chemical interaction of these adsorbed hydroxyl radicals. If this mechanism is accepted, it may be seen that the rate-determining step (equation 2) must occur four times to produce one oxygen molecule, so that the stoichiometric number is 4. Furthermore, hydrogen peroxide is not involved.

From investigation of the reduction of oxygen on carbon electrodes using oxygen-18 as label, Yeager *et al.*[6] found that the oxygen–oxygen bond is not broken and hydrogen peroxide is the final product. It is generally known that carbon is a poor catalyst for the decomposition of hydrogen peroxide. If a good catalyst for hydrogen peroxide decomposition such as platinum is used as the cathode material, water is the final product; but hydrogen peroxide builds up in solution to a steady-state concentration of about 10^{-6} M[1,2,7]. These results suggest that the reduction of oxygen on platinum proceeds through the stable intermediate, hydrogen peroxide. A possible mechanism is as follows. Oxygen is adsorbed on the electrode surface, and the rate-determining step is the discharge of the first electron[2]:

$$(O_2)_{ads} + e \rightarrow (O_2^-)_{ads} \quad (5)$$

This step is followed by the reaction with a hydrogen ion:

$$(O_2^-)_{ads} + H^+ \rightarrow (HO_2)_{ads} \quad (6)$$

After discharge of another electron and the reaction with another hydrogen ion, a molecule of adsorbed hydrogen peroxide is produced:

$$(HO_2)_{ad} + e \rightarrow (HO_2^-)_{ads} \quad (7)$$

and

$$(HO_2^-)_{ad} + H^+ \rightarrow (H_2O_2)_{ads} \quad (8)$$

The peroxide may desorb into solution or may undergo catalytic decomposition to oxygen and water:

$$2(H_2O_2)_{ads} \rightarrow (O_2)_{ads} + H_2O)_{ads} \quad (9)$$

The oxygen formed from the hydrogen peroxide may undergo the reactions shown in equations 5–8, and effectively four electrons will have been passed and oxygen will have been reduced to water. If the electrode surface has adsorbed oxygen on it, such as a partial layer of platinum–oxygen[8], produced by pre-anodization, the decomposition of hydrogen peroxide occurs through interaction with the platinum–oxygen layer as suggested by Bianchi *et al.*[7]:

$$H_2O_2 + Pt\text{–}O \rightarrow H_2O + O_2 + Pt \quad (10)$$

When the platinum–oxygen layer has been reduced, hydrogen peroxide is decomposed by a local cell mechanism[9] as first described by Gerischer and Gerischer[10]:

$$H_2O_2 + 2H^+ + 2e \rightarrow 2H_2O \quad (11)$$

and

$$H_2O_2 \rightarrow O_2 + 2H^+ + 2e \quad (12)$$

In the cathodic case a stoichiometric number of 2 is expected. The stoichiometric number, ν, may be determined from the anodic (b_a) and cathodic (b_c) Tafel slopes by the relationship:

$$\nu = \frac{4F}{RT}\left(\frac{b_a b_c}{b_a + b_c}\right) \quad (13)$$

only if the activated complexes for the anodic and cathodic reactions are the same as pointed out by Parsons[11]. Because on platinum electrodes the activated complex involves a single-bonded oxygen as shown in equation 2 at the anode, but a double-bonded oxygen (equation 5) at the cathode, equation 13 cannot be used, and such calculations are meaningless.

However, Bockris and Huq[1] were able to observe experimentally the reversible oxygen potential, 1·23 V, for about 1 h on platinum electrodes under open-circuit conditions in a rigorously purified system. They suggested that these observations had not been made before because others had worked with impure systems.

When a clean platinum electrode was placed in a purified acid solution[8], the reversible potential was not observed; and the rest potential was explained in terms of a local cell mechanism composed of the oxygen/water reaction, equation 1, and the platinum/platinum–oxygen reaction:

$$Pt\text{–}O + 2H^+ + 2e \rightleftharpoons Pt + H_2O \quad (14)$$

Recently, it was found[12] that the reversible oxygen potential could be observed for extended periods of time on a platinum electrode which had been treated with concentrated nitric acid. This treatment with nitric acid, it was suggested, produces a complete electronically conducting layer of adsorbed oxygen. In this way, the mixed potential mechanism is suppressed, and the surface is both electronically conducting and inert to oxygen. Consequently, a potential of 1·23 V is observed.

It is to be noted that those electrodes on which Bockris and Huq observed 1·23 V at open circuit were heated at 500° C for 2 h just before they were plunged into the electrolyte which, it is contended, produced a complete layer of electronically conducting platinum–oxygen. Similarly, Watanabe and Devenathan[13] observed the 1·23 V only after exposing the clean electrode to pure oxygen for 48 h.

Therefore, another condition as well as the rigorous control of impurities maintained by Bockris[1] must be imposed on the platinum–oxygen acid system before the reversible oxygen potential can be observed. The platinum surface must be covered by a complete layer of platinum–oxygen.

When the nitric acid-treated platinum electrode, referred to as a platinum–oxygen–alloy electrode[14], is polarized at very low current densities, a plot of the potential as a function of current density gives a straight line (see Fig. 1 of ref. 15) which passes from anodic to cathodic polarization through a potential of 1·23 V without a change of slope. As long as this electrode is not polarized beyond about 50 or 60 μamp/cm^2, the

system is stable; and the polarization curve is reproducible. At high anodic or cathodic current densities, the complete film of platinum–oxygen is impaired; a mixed potential mechanism sets in; and the reversible electrode is destroyed. Peroxide is not detected when a platinum–oxygen–alloy electrode is cathodized[15]. As the rest potential is 1·23 V, the slope of the anodic and the cathodic branches of the voltage-current (E–i) curve is the same, and hydrogen peroxide is not detected with cathodic polarization, it is concluded that a platinum electrode completely covered by a conducting layer of platinum–oxygen produced either by exposure to nitric acid[12] or to pure oxygen[1,13] is a true reversible electrode. Therefore, the oxygen–oxygen bond must be broken at the cathode before an electron is transferred instead of afterwards as in the mechanism described by equations 5–9.

At the reversible platinum–oxygen electrode, the potential is much more noble (by 200–300 mV) than at an irreversible platinum/oxygen electrode, as local cell action is missing. Also, oxygen is adsorbed at the reversible electrode on a complete layer of platinum–oxygen symbolized by Pt–O(O_2). Under these circumstances of high potential, the electrode surface is capable of breaking the oxygen–oxygen bond before electron transfer takes place. A possible mechanism may be visualized as follows. The oxygen–oxygen bond is broken,

$$\text{Pt–O}(O_2) \rightarrow 2\text{Pt–O(O)} \qquad (15)$$

followed by the reaction with an adsorbed water to form adsorbed hydroxyl radicals:

$$\text{Pt–O(O)} + \text{Pt–O}(H_2O) \rightarrow 2\text{Pt–O(OH)} \qquad (16)$$

Finally, water is formed from the discharge of absorbed hydroxyl radicals:

$$\text{Pt–O(OH)} + H^+ + e \rightarrow \text{PT–O}(H_2O) \qquad (17)$$

It can be seen that the cathodic mechanism, equations 15–17, is the reverse of the anodic mechanism, equations 2–4, as originally suggested by Bockris and Huq[1].

These mechanisms, however, can occur only on clean platinum electrodes covered by a complete layer of platinum–oxygen at low current densities, because it was observed[15] that after high anodic or cathodic polarization the system did not return to its original state. With anodic polarization, current goes into converting platinum–oxygen sites into platinum dioxide sites (see Fig. 4 of ref. 15) which impairs the complete layer of platinum–oxygen, so that under open-circuit conditions the local cell mechanism takes place with a resulting loss of potential. With cathodic polarization, the platinum–oxygen layer is also partially reduced, destroying the conditions for a reversible electrode. As a result, any kinetic data, such as Tafel slopes and i_0 values, obtained from polarization data at relatively high current densities do not relate to the reversible but to the irreversible platinum/oxygen electrode where the anodic and cathodic mechanisms are not the same. Values of ν calculated from equation 13 are meaningless. Also ν values determined from low current density data using

$$\nu = \frac{4Fi_0}{RT}\left(\mathrm{d}\eta/\mathrm{d}i\right) \qquad (18)$$

(where i_0 is the exchange current and $\mathrm{d}\eta/\mathrm{d}i$ is the slope of the linear E–i curve, see Fig. 1 of ref. 15), are doubtful because i_0 as obtained from the Tafel slope is unreliable. Values of i_0 between 10^{-9} and 10^{-10} amp/cm^2 recorded in the literature[1,2,4,13] relate to the irreversible platinum/oxygen electrode. The i_0 for the reversible platinum/oxygen electrode is between 10^{-5} and 10^{-6} amp/cm^2 (see Fig. 3 of ref. 15).

In conclusion, one must distinguish between two types of platinum/oxygen electrodes. The irreversible platinum/oxygen electrode, which is the one normally prepared, is a polyelectrode[16]; the rest potential is a mixed potential[17]; the anodic mechanism, equations 2–4, is different from the cathodic, equations 5–9; and in the reduction of oxygen, electrons are transferred before the oxygen–oxygen bond is broken, producing the stable intermediate, hydrogen peroxide. The reversible platinum/oxygen electrode prepared only by special techniques[1,12,13] is a single electrode[16]; the rest potential is determined by the oxygen/water reaction, equation 1; the anodic, equations 2–4, and the cathodic, equations 15–17, mechanisms are the reverse of one another; in the reduction of oxygen, electrons are transferred after the oxygen–oxygen bond is broken; and the only intermediate involved is the unstable adsorbed hydroxyl radical.

ELECTRICAL CONTROL OF BEHAVIOUR BY PROGRAMMED STIMULATION OF THE BRAIN

By Dr. LAWRENCE R. PINNEO

Delta Regional Primate Research Center, Tulane University, Covington, Louisiana

The ability to control electrically the behaviour of animals would greatly aid physiologists and behavioural scientists in the investigation of the neural mechanisms of motor activity, and the normal behaviour patterns involved in purposive movement and social interaction. Quite a number of experiments have shown that such an approach is feasible. For example, Hess[1] has shown that a wide variety of movements of the head, forelegs, hindquarters, and the muscles of the face may be elicited by electrical stimulation of diencephalic structures. Hess, and others, have further demonstrated that a "normal" progression of behaviour in time such as feeding, attack, and avoidance, can be initiated by electrical stimulation in one site. von Holst and von St. Paul[2,3] were able to obtain both simple movements and complex barnyard behaviour patterns in chickens by stimulation of sites in the brain stem. These forms of behaviour included sitting, standing, preening, seeking and eating food and drinking water, escaping from predators, and the like. Delgado[4] found that long term stimulation of the red nucleus of

rhesus monkeys evoked a reliable sequence of behaviour such as bipedal locomotion, climbing, vocalization, and social interactions.

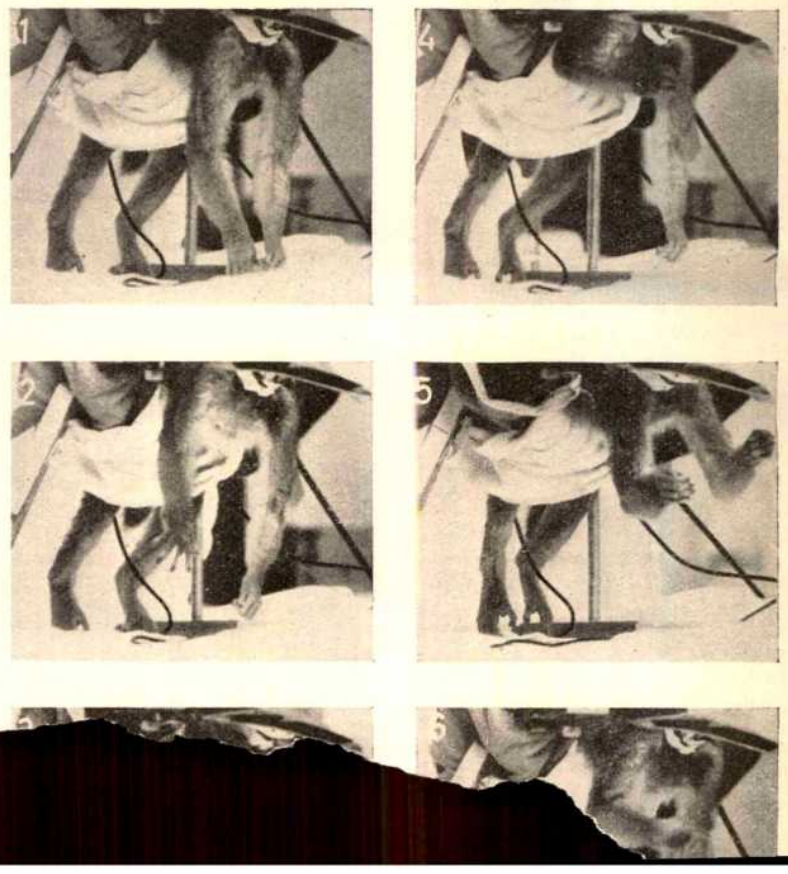
The difficulties with the results of these experiments are three. (1) In normal behaviour a given group of muscles are used in a wide variety of ways, but stimulation as in the experiments described does not allow for any variability in behaviour using the same electrodes. Rather, it appears that in most instances behaviour was initiated by stimulation of centres or pathways pre-existing at a high level of integration in the nervous system. (2) Unfortunately, histological analysis of the brain sites subserving the movements elicited in these experiments has not revealed a simple spatial separation into discrete centres, each of which might represent one specific function. (3) The type and complexity of the movements depended to a large extent on antecedent conditions, such as sleeping versus awake, reclining versus erect.

What is obviously needed, then, is a set of discrete brain centres which, whenever stimulated, always results in relatively simple movements (that is, at a relatively low level of integration), and the same movements each time the sites are stimulated. By combining or programming several different simple movements in time, one might produce a particular sequence of behaviour; by changing the programme, but still stimulating the same sites, a different sequence of behaviour would result.

A clue to this possible solution of the problem is suggested by experiments of Brodal, Pompeiano and others[5–7] on decerebrate rigidity. Their work showed that electrical stimulation of cerebellar nuclei, vestibular nuclei, and other nuclei in caudal brain stem produces unitary movements such as flexion or extension of a paw, foreleg or hip. Though simple, these elementary responses still require co-ordinated integration of synergistic and antagonistic systems, often involving as many as thirty different muscles. Nevertheless, the movements were quite discrete, and it was found that many of the nuclei were somatotopically organized, that a given locus of stimulation always produced the same kind of movement, and that some of the same movements could be produced by stimulation in more than one nucleus. To me, these results seemed admirably to answer the question of how to programme stimulation of the same sets of muscles in order to control many different behaviour sequences.

To this end, our first attempts have been directed toward control of the right arm and hand of a squirrel monkey (*Saimiri sciureus*) in the performance of various actions and to the determination of the level of organization of these movements in the brain. Preliminary experiments were carried out on five cats and six monkeys. A single concentric electrode was used stereotaxically[8] to explore various sites in animals anaesthetized with pentobarbital sodium (30 mg/kg in cats) and seconal (20 mg/kg in monkeys), in order to determine the type of movement elicited at each locus and the optimum electrical parameters required for the best results. Electrodes consisted of an outer stainless steel tube (0·5 mm outer diameter) insulated to within 1 mm of the end, and an inner stainless steel wire (0·1 mm outer diameter) insulated to its tip; electrode tip separation was 1·0 mm. Stimulation was provided with a Grass *S*-4 stimulator through an isolation unit, and the stimulating current monitored on a 'Tektronix 565' cathode-ray oscilloscope by measuring the *IR* drop across a 1,000 ohm resistance in series with the electrode. Exploration extended to 1 mm steps from stereotaxic co-ordinates *P* 3·0 to *P* 7·0 in the anterior–posterior plane, laterally from 0·5 to 3·5 on the right side, and from +1·0 to −13·0 in the horizontal plane.

Nuclei stimulated included the interpositus, fastigial, and dentate of the cerebellum, and the superior, medial, lateral, and inferior vestibular nuclei, as well as other brain stem nuclei (Fig. 1).



In each anterior–posterior–lateral stereotaxic locus, the stimulating electrode was moved vertically down 0·5 mm at a time, and pulsed current increased slowly from zero to 800 μamp, base-to-peak. Whenever a movement was elicited by a high current value, invariably the same movement was produced at a relatively low current value by simply lowering the electrode by 1·0–2·0 mm, or by placing the electrode laterally at the same depth. That locus where the lowest current produced the maximum movement effect was judged to be the site responsible for the movement, and the current used as the "threshold" current. Optimum electrical parameters at such threshold sites were usually found to be 200–300 rectangular pulses per second, 0·1–1·0 msec duration, and 50–200 μamp base-to-peak, monophasic with the inner electrode—the cathode. Each site was very specific, for if the electrode was moved up or down during threshold stimulation as little as 100μ the elicited movement ceased; it could be re-elicited by an increase in current or repositioning of the electrode at the former site. In all the locations examined, the mechanical effect of movement was proportional to current strength so that very finely graded movements could be obtained.

Some of the simple, non-programmed movements produced by this exploratory stimulation in an anaesthetized monkey are shown in Fig. 2; the position of the stimulating electrode in each case is indicated in Fig. 1. At any given locus an increase in current significantly above threshold (for example, up to 800 μamp in photographs 4, 5 and 6 of Fig. 2), produced more than one fragmentary response. Presumably this resulted from spread of current to adjacent sites, as movement of the electrode up, down or laterally produced each movement separately at low current values. In addition to the grasping and extension of the fingers, the extension and flexion of the limbs at the wrist, elbow, shoulder, ankle, knee, or hip, we also found sites for opening and closing the mouth as in mastication (site No. 10), movement of the tongue in or out as in licking (not shown), curling or sideways movement of the tail (not shown), and were able to control heart rate and rate and volume of respiration.

Programmed stimulation was achieved in three additional squirrel monkeys. Unfortunately, all three died as a result of oedema of the brain stem before motion picture camera was avail record their movements. Ho movements can be descri the technique. U trodes were chr

waveform and pulse generators) and additional stimulators to produce the desired effects. Most of the sequences chosen were based on the naturally occurring movements observed in the awake animal before implantation, and the particular simple movements we were able to elicit at each electrode site after implantation. Several arbitrary combinations were also used to explore other possible movements not previously observed in the monkeys. The elementary movements in the three monkeys were very similar when stimulated in homologous loci, and a given sequence of stimulation produced essentially the same sequence of behaviour in each animal. Abnormally appearing temporal sequences or "slow motion" behaviour could be obtained as well.

In one programme of stimulation (sequence 7 for 0·3 sec; 7 & 2, 0·1 sec; 7 & 8, 0·6 sec; 3, 0·2 sec; 3 & 9, 0·2 sec) the awake monkey would grasp an object (for example, monkey chow) with its right hand and rapidly and smoothly bring the object to its mouth. This sequence could be repeated as often as desired, and the movements could not be discriminated by observers to be different from that which occurred when the animal voluntarily performed the same act. Using the same set of electrodes, different programmes produced different sequences of movement. For example, sequence 9, 0·1 sec; 9 & 7, 0·5 sec; 9 & 7 &

2, 0·1 sec; 9 & 7 & 8, 0·3 sec, produced extension of the arm outward and upward as in reaching or climbing, while sequence 9, 0·1 sec; 9 & 11, 0·4 sec; 7, 0·4 sec; 9 & 3 & 11 & 2, 0·4 sec; etc., produced extension of the arm backward over the body with a back-and-forth movement (as in scratching) at the base of the tail. It appeared that an almost endless repertoire of sequential movements could be elicited in this limb by simply changing the programme and stimulus duration of the same set of electrodes. In all cases, the electrical stimulation over-rode and pre-empted any simultaneous voluntary movement of the animal, and a movement sequence could be elicited in its essential form whatever the position of the animal (provided the limb was free to move) and whether the monkey was asleep, awake, or under anaesthesia.

At the levels of the central nervous system where these stimulations were performed, it is most unlikely that individual nerve fibres were selectively excited and in the proper temporal sequence to produce such complex and organized movements. Rather it would seem that, as Delgado[9] has suggested, behaviour is composed of integration of "behavioural fragments", and each "behavioural fragment" has a specific neuronal organization pre-existing in an anatomical structure. The organized structures in this investigation were presumably triggered by the increase in tonic activity at the sites of electrical stimulation, giving pre-eminence to one or more functional motor responses to the exclusion of others.

In order to isolate the level of the organization of the elementary responses, various lesions were made in several animals anterior to the electrode sites. Destruction of the left motor cortex for the right hand and arm in one of the chronic squirrel monkeys produced paralysis to voluntary movement in that limb as it does in man. Yet, both single and programmed movements were produced after the lesion that did not differ in any way from those elicited before the monoplegia. In two of the acute monkeys, in which electrodes were located in the vestibular nuclei at the level of P 5·0, a complete section of the brain stem immediately anterior to the stimulating electrode did not alter the movements elicited by stimulation before the section was made. From histological investigations in another animal, it was found that the electrode producing integrated movement had actually been in the spinal cord at about C 2. Apparently, the organization of these elementary movements exists at the level of the spinal cord, and they are elicited directly by way of efferent pathways or reflexly by stimulation of afferent fibres.

Apart from the oedema produced in the chronic animals (which we are trying to correct by using smaller, multiple electrodes in a single chain), these results suggest that programmed stimulation of the brain can be a powerful research tool in initiating, modifying, and controlling behaviour. For example, we are at present mapping the entire neuraxis in order to determine the type, complexity, and extent of movement that may be elicited at each site and the electrical parameters required. Simultaneously, we are observing by means of cinematography the complex behaviour of primates in isolation and in social interrelations with other primates. By combining the two investigations with programmed stimulation in chronically implanted animals, we hope rigorously to control their movements in order to determine the fundamental nervous mechanisms governing purposive motor behaviour. Because the level of integrative organization of the elementary responses elicited in this investigation is in the caudal brain stem and spinal cord, it may even be possible in the future to stimulate the brains of human beings in a similar way afflicted with paralysis from cerebral strokes, Parkinsonism, epilepsy and other diseases of the central nervous system, in order to restore normal motor function and voluntary control of purposive movement.

This work was supported by a U.S. Public Health Service grant from the Division of Research Facilities and Resources. I thank Drs. J. M. R. Delgado, William Mason, Ronald Melzack, and A. J. Riopelle for their critical comments on an earlier draft of this article.

AN OPERATOR MODEL OF CROSSING-OVER

By DR. H. L. K. WHITEHOUSE
Botany School, University of Cambridge

RECENT models of the mechanism of [illegible] fitted the hypothesis, but it was postulate breakage of single nucleot[illegible]stulate that there was a charac- followed by annealin[illegible]tion of the nucleotide-chains from homologous [illegible]ch gene, and these fre- According to the [illegible]end to another in

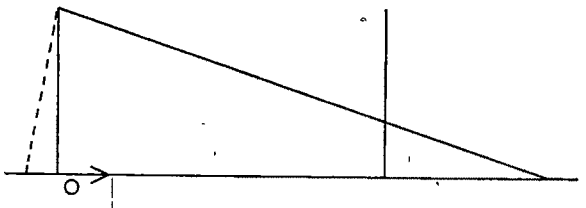

Fig. 1. Diagram to show the postulates of the operator model of crossing-over. The vertical lines show the ends of a gene, the unbroken sloping line the extent of formation of cross-over (and double cross-over) hybrid DNA originating from primary breaks at the gene end at the top of the slope, and the broken line shows the extent of double cross-over hybrid DNA in a reverse cross-over. The letter *O* and the arrow show the position of the operator and the direction of opening of the gene

bring this about has much shorter hybrid DNA segments. The process of reverse crossing-over would require dissociation of the nucleotide-chains, synthesis and hybrid DNA formation on the other side of the primary breakage-point ('opening-point') from which the original cross-over was initiated. These hybrid DNA segments would extend a short distance into the neighbouring gene on the other side. This model of crossing-over is shown diagrammatically in Fig. 1.

Hastings and I[4] pointed out the resemblances between the postulates of the polaron hybrid DNA model and the likely events in messenger RNA (*m*RNA) formation. It remains uncertain whether *m*RNA is synthesized along the intact duplex DNA of the gene (or group of genes forming an operon), or whether a single chain acts as the template after breakage of one chain at the end of the gene (or the operon) and dissociation of the chains over its length. In either event, it would seem that a recognition site, that is, an operator, must exist at one end of the gene (or the operon), where synthesis of the messenger is initiated. According to Jacob and Monod[6], the operator is not only the initiation site for the transcription of the messenger, but also the receiving site for a specific repressor produced by a regulator gene. Through the mediation of the operator, the repressor is thought to block the initiation of transcription.

Like transcription, the recombination mechanism proposed here requires recognition of one particular end of each gene. Moreover, there is evidence (given later) for a control mechanism for recombination similar to that postulated by Jacob and Monod[6] to control transcription. In view of these similarities, it is proposed to call this recombination mechanism an operator model of crossing-over. The possibility that the recombination and transcription operators are identical is discussed later.

Many of the predictions of the operator model resemble those of the polaron model. The chief differences concern the patterns of polarity in recombination within the gene, and the interrelations of neighbouring genes in recombination.

Polarity in Intragenic Recombination

Two primary patterns of intragenic polarity are predicted by the operator model, depending on the direction of dissociation of the DNA in the neighbouring gene beyond the terminus (non-operator) end of the first gene. If this neighbour showed the same direction of dissociation, the first gene would have all its cross-over hybrid DNA arising from the operator end, whereas if the neighbour showed the opposite direction, both genes would have cross-over hybrid DNA entering from both ends. Allowing also for the effects of reverse cross-overs, eight patterns of recombination within genes are predicted, as shown in Fig. 2. The alternatives depend on the orientation of the gene and of its neighbours on each side.

Hastings and I[4], from an investigation of published data, found two primary patterns of intragenic recombination such as this model predicts. In unipolar genes all the dissociation of nucleotide-chains leading to hybrid DNA formation and crossing-over appeared to originate from one end of the gene, while in bipolar genes hybrid DNA appeared to originate from primary breaks at (or beyond) either end of the gene, but with one end predominating. In Table 1, nine genes are classified in terms of these patterns of polarity in recombination, and also with respect to the predominant direction of the polarity relative to the position of the centromere, where this is known. It is evident that both unipolar and bipolar genes may be orientated in either direction relative to the centromere. As already mentioned, the two basic patterns of polarity within the gene correspond to the predictions of the operator model, genes 1, 2, 7 and 8 in Fig. 2 being unipolar and 3–6 bipolar. Moreover, the genes *ad*-9 (adenine-9) and *paba*-1 (*para*-aminobenzoic acid-1) in *Aspergillus nidulans* are thought to be neighbours, and their patterns of polarity are appropriate to a bipolar pair such as 3 and 4 (or 5 and 6) in Fig. 2. The model predicts that if the two ends of a gene are denoted by *O* (operator) and *T* (terminus), at the *T* end of a unipolar gene the neighbouring gene has its *O* end nearest, while the *T* neighbour of a bipolar gene has its *T* end nearest. Applied to *ad*-9 and *paba*-1, it is suggested that the *T* ends of these genes adjoin one another.

Table 1. Patterns of Intragenic Polarity in Recombination

Predominant direction of polarity with respect to the centromere	Pattern of polarity: Unipolar	Pattern of polarity: Bipolar
Proximal	*Saccharomyces cerevisiae* *hi*-1 (ref. 7)	*Aspergillus nidulans* *ad*-9 (ref. 8)
Distal	*Neurospora crassa* *me*-2 (ref. 9)	*Aspergillus nidulans* *ad*-8 (ref. 10); *paba*-1 (ref. 11); *Neurospora crassa* *cys* (ref. 12); *his*-5 (ref. 13)
Unknown	*Ascobolus immersus* series 46 (ref. 14)	*Ascobolus immersus* series 19 (ref. 14)

Genes are expected to vary in length depending on the length of the polypeptide for which they code. If the length of hybrid DNA arising from an opening-point were approximately constant in terms of nucleotide-pairs (ignoring the effects of mutations within the hybrid region), the pattern of recombination within a gene would be expected to depend to some extent on the length of the gene and of its immediate neighbours. The rather slight evidence of polarity in the gene *pan*-2 (pantothenic acid-2) in *Neurospora crassa* investigated by Case and Giles[15] would be accounted for if it and a neighbour formed a bipolar pair and if one or both of them were comparatively short. A similar explanation might apply to *hist*-3 (histidine-3) investigated by Webber[16]. By the same argument, more than two genes might sometimes be included in the hybrid DNA from an opening-point.

On the polaron hybrid DNA model, the chromosome was divided into segments or polarons defined by the opening-points and within which recombination was entirely by conversion. On the operator model, polarity is a consequence of the fixed direction of opening in each gene and the term polaron ceases to have a precise meaning,

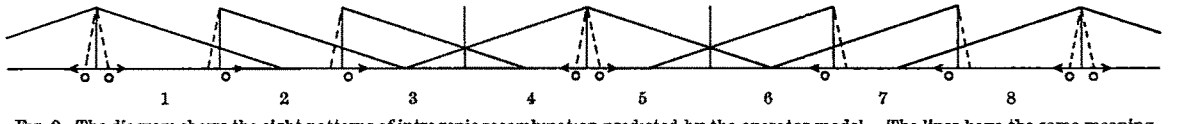

Fig. 2. The diagram shows the eight patterns of intragenic recombination predicted by the operator model. The lines have the same meaning as in Fig. 1

because hybrid DNA may extend through one gene into the next and so may pass another potential opening-point.

Reverse Cross-overs

If a sufficient number of allelic mutants were available in a recombinant selection experiment with outside markers, it is likely that some of the alleles would be close to the ends of the gene, and these might allow detection of reverse cross-overs, indicated by the broken lines in Fig. 2. The operator model predicts that an excess of parental combinations for outside markers, such as a reverse cross-over would give, is expected in unipolar genes either at the *T* end (genes 2 and 7 in Fig. 2) or at both ends (genes 1 and 8) and in bipolar genes either at the *O* end (genes 4 and 5) or at neither end (genes 3 and 6).

In the gene in which recombination has been investigated by prototroph selection using the largest number of mutant sites, namely, *me*-2 (methionine-2) in *Neurospora*, Murray[9] found an excess of parental arrangements for the outside markers when one of the methionine mutants was at the distal end of the gene map. This would be the *O* end on the operator model, since *me*-2 seems to be unipolar with distal polarity. There is also evidence from her data that these reverse cross-overs have shorter hybrid DNA segments than the primary cross-overs (see p. 80 of ref. 5). The model predicts reversed polarity at the other end of the gene (compare with gene 8 in Fig. 2), and this Murray[17] has now found but without the expected excess of parental combinations.

Fogel and Hurst[7] have found a pattern of recombination in *hi*-1 (histidine-1) in *Saccharomyces cerevisiae* similar to that in *me*-2 in *Neurospora*, except that *hi*-1 has proximal polarity. When the mutant at either end of the *hi*-1 map is crossed with an allele, prototroph selection gives a higher proportion of parental combinations of outside markers than in most other allelic crosses, indicating reverse cross-overs at each end. There is also evidence that at the proximal end of the gene these reverse cross-overs have shorter hybrid DNA segments than the primary cross-overs, and that at the distal end they have reversed polarity. These findings are expected if *hi*-1 is like gene 1 in Fig. 2.

Investigation of recombination either by prototroph selection with allelic nutritional mutants, or by aberrant ascus selection with allelic ascospore colour mutants, and outside markers present, would allow further tests of the predictions of the model regarding reverse cross-overs, provided mutants were available situated near the ends of the gene as well as in other positions.

Bipolar Genes

The operator model predicts that at the *T* end of a bipolar gene hybrid DNA will arise about equally often from proximal and from distal directions (compare Fig. 2, junction of genes 3 and 4, or of 5 and 6). Such equality is evident at one end of all the bipolar genes that have been investigated by prototroph selection with outside markers (see diagrams in ref. 5). A further example is provided by the work of Smith[13] with *his*-5 (histidine-5) in *Neurospora*. His data are plotted in Fig. 3 using the method adopted by Hastings and myself[5]. The sequence of the mutant sites is shown at the top without the recombination frequencies, which among the crosses shown ranged from 2·1 per 10^5 viable ascospores for $K155 \times K542$ to 37·4 per 10^5 for $K516 \times K548$. The proximal end of the gene (which is in the right arm of linkage group IV) is to the left. For each allelic cross (indicated by the horizontal lines on the left of Fig. 3) the figures show the number of histidine-independent progeny which were found to have a parental combination of the outside markers. Only those crosses which gave more than twenty such progeny are included. The explanation of the graph is as follows.

If M/m and N/n denote the outside markers on the proximal and distal sides, respectively, of the nutritional locus, which has alleles 1 and 2 with 1 nearer to M/m and 2 to N/n, then from the cross:

$$\frac{M\ 1\ +\ N}{m\ +\ 2\ n}$$

the prototrophs may be of four genotypes, namely:

$$\begin{aligned} A:&\ M\ +\ +\ N \\ B:&\ m\ +\ +\ n \\ C:&\ m\ +\ +\ N \\ D:&\ M\ +\ +\ n \end{aligned}$$

Those of class *A*, that is, with additional recombination between the proximal allele (+/1) and the proximal outside marker (M/m), may have arisen through hybrid DNA reaching the site of allele No. 1 alone, such as might occur if the opening-point was on the proximal side of the gene. Conversely, prototrophs of class *B* might have arisen through hybrid DNA reaching the site of the distal allele (No. 2) alone, as from an opening-point on its distal side. Both *A* and *B* classes of prototroph might also have arisen as a result of hybrid DNA extending to both sites (1 and 2) from an opening point on the proximal or on the distal side of them. Hybrid DNA extending from one

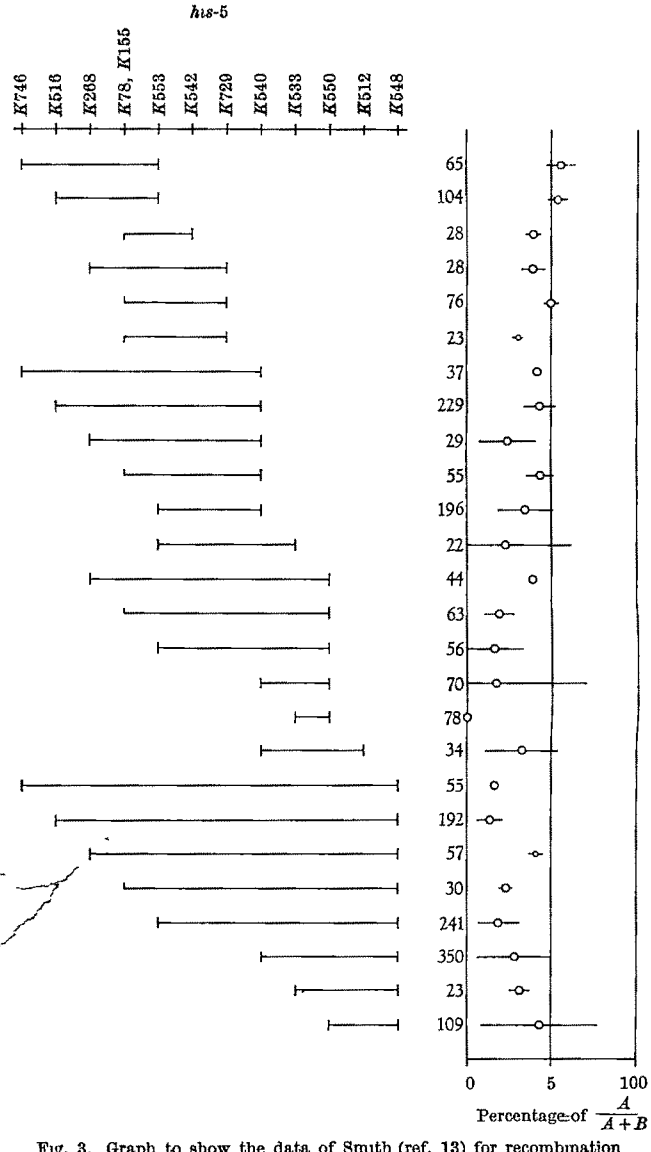

Fig. 3. Graph to show the data of Smith (ref. 13) for recombination within *his*-5 of *Neurospora crassa*. The diagram is explained in the text. Crosses involving *K*78 or *K*155 are distinguished by the horizontal line turning up or down, respectively

end to both sites is expected to contribute equally to the *A* and *B* classes. It is assumed that in the prototrophs any hybrid DNA entering the site underwent correction of mispairing to wild-type, as there was selection for this character. The points plotted in Fig. 3 show for different pairs of *his*-5 alleles the percentage frequency of class *A* prototrophs out of the total number of prototrophs with parental combinations of the outside markers ($A + B$).

Class *C* prototrophs could arise as a result of hybrid DNA reaching one site only (the proximal or the distal one) or both sites, while class *D* prototrophs require hybrid DNA to have reached both sites. Hybrid DNA at both sites is expected to give class *C* and class *D* with equal frequency. Hence $\frac{2D}{C+D}$ is a measure of the frequency of double-site hybrid DNA. The horizontal lines on each side of the points in Fig. 3 show for each cross the percentage frequency of class *D* prototrophs out of the total number of prototrophs with non-parental combinations of the outside markers ($C + D$). The total length of each line is $\frac{2D}{C+D}$ and is plotted on the same percentage scale as was used for the points in the graph, and with the half-length $\left(\frac{D}{C+D}\right)$ extending on each side of these points. In calculating $\frac{D}{C+D}$ a correction has been made for the distance of the outside marker genes, using the method proposed by Hastings and myself[5]. It has been assumed in making this correction that the proximal and distal markers (pyrimidine-3 and leucine-2) showed 1 per cent and 9 per cent recombination, respectively, with *his*-5. For most of the crosses the value of $C + D$ was approximately equal to that for $A + B$.

On the basis of these interpretations of the *A*–*D* classes, the horizontal lines on each side of the points in Fig. 3 show the contribution to the prototrophs due to hybrid DNA at both mutant sites. This hybrid DNA might have come from an opening point on the proximal or on the distal side of the sites. The interval between the left-hand end of each line and the left-hand axis $\left(\frac{A}{A+B} = 0\right)$ hybrid shows the frequency with which DNA has reached the proximal site alone, and similarly the right-hand interval shows the contribution from the distal site alone.

Smith's data suggest that hybrid DNA reaches the mutant sites within *his*-5 predominantly from the distal side of the gene, except near the proximal end, where the contributions of proximal and distal origin appear to be equal. As already indicated, this equality is expected on the operator model, for the *T* end of a bipolar gene.

Neighbouring Genes

The operator model makes different predictions from the polaron model concerning the behaviour of neighbouring genes in recombination. The polaron model predicted that *D* class prototrophs should not occur with two mutants in neighbouring genes, as the formation of hybrid DNA at both sites, such as the *D* class requires, would then need a double crossover from the opening-point, which would be between the sites, and this would give *A* or *B* class prototrophs, not *D*. On the operator model, however, *D* class prototrophs are expected with mutants in neighbouring genes, provided both mutants can be reached by hybrid DNA extending in one direction from an opening point. This is most likely to happen if the mutant site in one gene is near the end which adjoins the other gene. No *D* class would be expected when the neighbouring genes have adjoining operators, such as numbers 4 and 5 in Fig. 2.

A further prediction of the operator model is that the presence of a mutant in one gene may affect recombination in a neighbouring gene, as there is evidence that mutants interfere with the formation of hybrid DNA[3,5]. In particular, with a bipolar pair of genes such as 3 and 4 (or 5 and 6) in Fig. 2, the presence of a mutation in the proximal gene might be expected to weaken the proximal component of recombination in the distal gene, and conversely a mutant in the distal gene would be expected to reduce the distal component in the proximal gene.

Genetic Control of Recombination

Direct support for the operator model is given by the work of Jessop and Catcheside[18] with a gene *rec* (recombination) which affects recombination within the gene *his*-1 (histidine-1) in the right arm of linkage group V in *Neurospora*. In the presence of the recessive mutant *rec* in homozygous condition, the recombination frequency between *his*-1 mutants was more than ten times greater than when the dominant allele rec^+ was present. The recombination frequencies per 10^5 progeny with homozygous *rec* ranged from 3·61 for the allelic cross $K83 \times K627$ to 51·3 for $K83 \times K316$, and with rec^+ from 0·24 for $K566 \times K617$ to 3·96 for $K83 \times K616$. Moreover, the pattern of polarity in recombination within *his*-1 appears to be profoundly modified by *rec*. This is shown in Fig. 4, where the data are plotted in the same way as Smith's results for *his*-5 given in Fig. 3. Data relating to mutant *K*620 have been omitted as its map position is uncertain. In correcting for the distance of the outside markers (*amination* on the proximal side and *inositol* on the distal side), it has been assumed that they showed 3 per cent and 7 per cent recombination, respectively, with *his*-1. Where *spray* was used as proximal marker, its recombination frequency with *his*-1 was taken to be 7 per cent. The numbers in classes *C* and *D* taken together were usually about 40 per cent of the total prototrophs.

As with Fig. 3, the contribution to the prototrophs from each cross due to hybrid DNA at the proximal mutant site alone is indicated by the space between the left-hand end of each horizontal line and the vertical axis corresponding to $\frac{A}{A+B} = 0$. Similarly, the frequency of prototrophs due to hybrid DNA at the distal site alone is indicated by the space between the right-hand end of each line and the vertical line representing $\frac{A}{A+B} = 100$ per cent. The horizontal lines themselves show the contribution due to hybrid DNA at both sites, and this may be of proximal or distal origin. The simplest hypothesis is to assume that this double-site hybrid DNA shows the same proportion of proximal and distal origin as the single-site hybrid DNA.

It is evident that in the presence of homozygous *rec*, *his*-1 shows predominantly proximal polarity, while when rec^+ is present the recombination within *his*-1 appears to be entirely of distal origin. On the operator model this would be explained if rec^+ is a repressor for *his*-1 and if *his*-1 is opened at the proximal end. When rec^+ is present all the recombination within *his*-1 would then be due to hybrid DNA originating at an opening-point at the far end of the next gene to *his*-1 on the distal side, and extending through that gene to enter *his*-1 at the distal end. The recessive mutant *rec*, when homozygous, would prevent the *his*-1 repressor from functioning. This would explain both the effects of *rec*, that is, the much increased frequency of recombination within *his*-1 and the proximal polarity, assuming the *his*-1 operator is at the proximal end. Further data are needed to test whether the relatively little recombination within *his*-1 of distal origin is affected by *rec*.

Jessop and Catcheside[18] found that the recombination frequency between the outside markers *am* and *inos* was not lowered significantly when *rec* was replaced by rec^+.

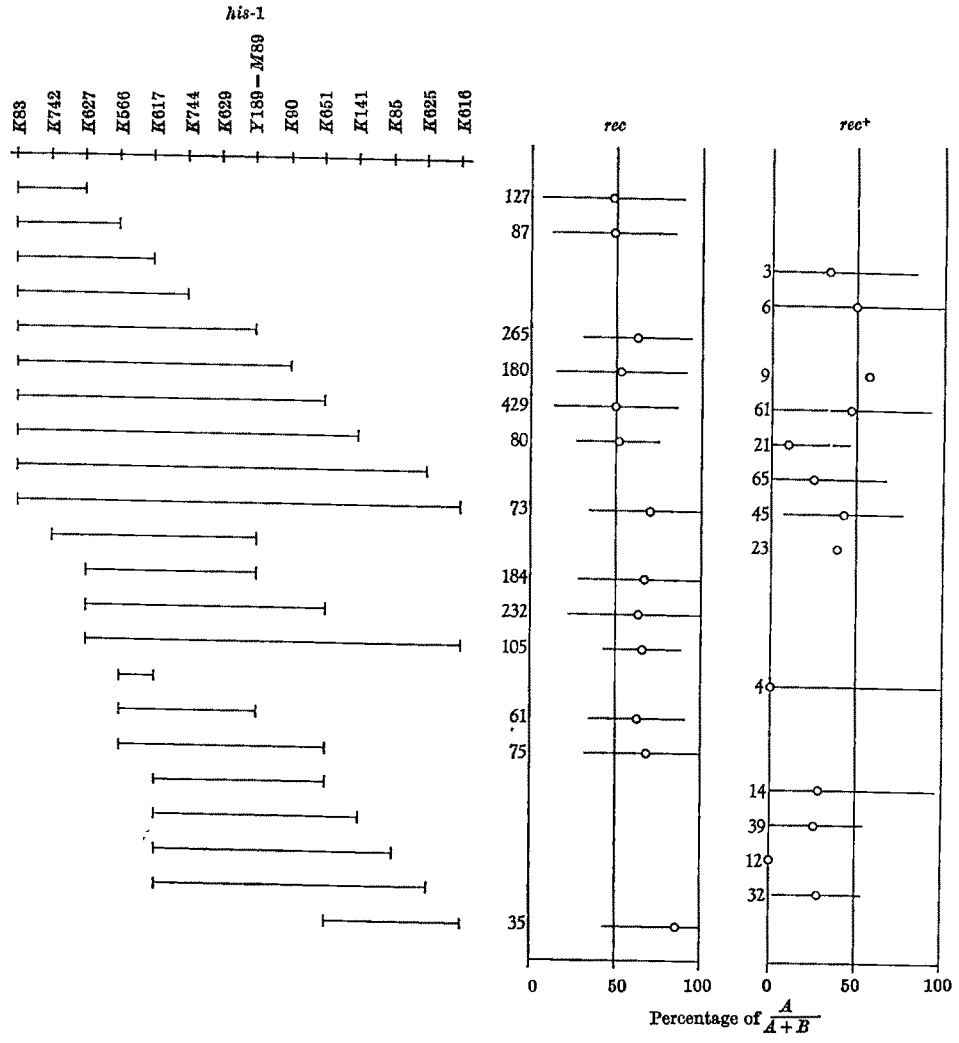

Fig. 4. Graph to show the data of Jessop and Catcheside (ref. 18) for recombination within *his*-1 of *Neurospora crassa*. The results with homozygous *rec* and in the presence of *rec*$^+$ are shown separately. The diagram is explained in the text

This might be accounted for if the effect of *rec* were masked by heterozygosity for repressors of recombination in other genes in the *am-inos* interval.

If the recombination and messenger operators were the same, *rec* would be expected to be a regulator for the functioning of *his*-1 as well as for its recombination. It is evident that study of genes such as *rec* may provide a direct approach to an understanding of the mechanism of control of gene activity, as well as to that of recombination. If for each gene there is a common operator for recombination and for transcription, the predominant direction of polarity in recombination (in the de-repressed gene) will coincide with the direction of messenger synthesis, since it has now been established that the messenger is synthesized from the operator end[19]. Furthermore, in an operon containing more than one gene, polarity in recombination is expected not to relate to the junctions between genes within the operon, but to the ends of the operon, and predominantly to one of them. These predictions provide a means of testing the hypothesis of a common operator for recombination and transcription.

It is significant that if dissociation of the nucleotide chains of DNA were to occur in the formation of *m*RNA, it would be necessary for the dissociation to extend beyond the end of the gene in order to expose the whole of its length for transcription. A similar extent of dissociation is postulated on the operator model of recombination, suggesting that if these mechanisms for transcription and recombination are true they may have had a common origin in evolution. It also appears significant that if crossing-over occurs by the opening of structural genes through their de-repression, this would explain the lack of crossing-over in heterochromatic regions of chromosomes[20] if, as evidence suggests, heterochromatin contains only regulator genes. Such genes appear to have other recombination mechanisms, which cause transposition to new locations[21] and specific factor transfer[22].

Summary

It is suggested that dissociation of nucleotide-chains, before the formation of hybrid DNA in crossing-over, occurs in a fixed direction from one specific end of each gene, and extends through it into the next gene. On this operator model, unipolar and bipolar genes are determined by the orientation of the neighbour. It is further postulated that recombination events within a gene, associated with a parental arrangement for marker genes outside, are due to a second or reverse cross-over, with short hybrid DNA segments extending in the opposite direction into the neighbouring gene on the other side. It is shown how this model can account for a number of previously unexplained features of recombination, including data on genetic control. Experimental tests of the model are

outlined. The possibility is discussed that for each structural gene (or group of genes forming an operon) there may be a common operator and a common regulator gene for both transcription and recombination.

I thank Dr. C. Bresch, Dr. F. Cooke, Dr. H. Gutz, Dr. P. J. Hastings and Dr. S. F. H. Threlkeld for invaluable discussion and criticism during the preparation of the manuscript, and Dr. S. Fogel, Dr. D. D. Hurst and Dr. N. E. Murray for permission to refer to their unpublished work. I thank Mr. G. J. Clark for preparing the diagrams.

Note added in proof. I am grateful to Dr. J. R. S. Fincham for directing my attention to the work of Luzzati[23], who has found evidence for a common regulation mechanism for recombination and transcription. Luzzati *et al.*[24] discovered that non-reciprocal mitotic recombination between alleles at the *ad*-3 locus in *Saccharomyces cerevisiae* is inhibited by histidine, which is an end-product of a biosynthetic pathway affected by this gene, since *ad*-3 mutants require adenine and histidine for growth. Luzzati[23] has now found, not only that this inhibition of conversion is specific to L-histidine and to the *ad*-3 gene, but also that a dominant mutant, *S*9, and a recessive mutant, *s*15, not linked to one another or to *ad*-3, suppress the requirement for histidine but not that for adenine in *ad*-3 mutants, and also inhibit recombination within *ad*-3, whether histidine is present or not. A dominant mutant, *S*24, apparently due to mutation within *ad*-3, suppresses the histidine requirement but does not affect the intragenic recombination, which is inhibited when histidine is added. Detailed interpretation of these results requires more information than is known at present about the function of the *ad*-3 and suppressor loci, but a relationship between recombination within a gene and its activity is manifest.

HYPERPLOIDY EFFECT OF LYMPHOCYTE EXTRACT ON FIBROBLASTS *IN VITRO*

By DR. P. J. FIALKOW and PROF. S. M. GARTLER
Departments of Medicine (Division of Medical Genetics) and Genetics, University of Washington, Seattle, Washington

A RELATIVELY high frequency of thyroid autoantibodies has recently been observed in patients with diseases characterized by chromosomal aberrations, such as gonadal dysgenesis[1–3] and Down's syndrome[4]. These observations together with the older reports of thyroid dysfunction and goitre in the mothers of children with Down's syndrome[5–7] led us to suggest that immunological aberrations in a parent may be related to the production of chromosomal abnormalities in the offspring[8]. Afterwards, more evidence along these lines was provided by the demonstration of a significantly increased frequency of thyroid autoantibodies in the mothers of children with Down's syndrome[9]. To examine further the possibility that immunological mechanisms predispose to chromosomal aberrations, an investigation of the hyperploidy effect of lymphocyte extracts on mitoses of fibroblasts in cell culture was undertaken.

Human lymphocyte-rich plasma was prepared under sterile conditions by allowing the red blood cells to sediment and the polymorphonuclear cells to adhere to glass[10]. The cells were washed three times in a phosphate isotonic buffer (*p*H 7·1), diluted to a concentration of 2 or 4 × 10^6 lymphocytes/ml., and crude extracts prepared by rapid freezing and thawing ten times. The extracts were stored frozen and retained their activity for at least 3 weeks. No relationship between the extent of contamination by polymorpho-nuclear or red blood cells and the degree of hyperploidy was evident. No effort was made to determine what, if any, part of the hyperploidy effect resulted from monocytes. The cell culture and cytological techniques used in these experiments have already been described[11,12].

Varying doses of extract were added directly to 80,000–100,000 freshly transferred fibroblasts growing in Waymouth's medium supplemented with 15 per cent foetal calf serum. After 3–5 days the cells were collected and scored for hyperploidy. To allow the screening of a large number of cells, slides were screened under low power and if a mitosis appeared to be hyperploid, the chromosomes it contained were counted under higher magnification. Cells with 55 or more chromosomes were scored as abnormal. Fifty-five was chosen as the dividing line since cells with that number of chromosomes usually appear hyperploid under low power whereas cells with fewer chromosomes can be missed. No effort was made to score for the type of hyperploidy (for example, triploidy or tetraploidy) except in the case of endoreduplication.

At the time of use the cultures varied in age from two to twenty-seven transfers and for each experiment duplicate cultures not treated with lymphocyte extract served as controls. For each of these, and for each dosage of extract, 500–1,000 metaphases were usually scored for hyperploidy. In order to get an estimate of the error involved in the culturing and scoring procedure, fourteen replicate pairs were sub-cultured and scored separately. The mean difference between pair members was 0·4 per cent with a standard deviation of 0·31 per cent. The range was from 0 to 1 per cent.

In untreated fibroblast cultures obtained from skin, the percentage of mitoses which were hyperploid by our criteria ranged from 2 to 17 but most cultures had 3–5 per cent hyperploidy. Fibroblasts obtained from muscle seemed to have higher control levels. Endo-

reduplicated mitoses were observed in seven of twelve untreated skin cultures and in three of four untreated muscle cultures.

Lymphocyte extracts from four patients with "autoimmune" diseases were tested on allogeneic fibroblasts and the results are given in Table 1. Subjects 1, 3 and 5 have Hashimoto's thyroiditis and subject 6 has "autosensitization" eczema. Subject 7 is also included in Table 1 although, as indicated later, her illness is not clearly defined. In each case significant increases were observed (greater than three times the standard deviation of the experimental error obtained from the replicate cultures as already mentioned). Moreover, there was a strong correlation with dosage of lymphocyte extract.

Increases in endoreduplication were observed in most experiments. These increases appeared to be correlated with the overall degree of hyperploidy and may not result from a separate effect.

In order to see whether the hyperploidy effect was specific for extract obtained from patients with "autoimmune" diseases, lymphocyte extracts from eleven "normal" subjects (for example, no known "autoimmune" or chromosomal disorders) were tested on allogeneic fibroblasts. Thirteen of fifteen allogeneic extract-fibroblast combinations produced significant responses, and again there was a strong correlation with dosage (Table 2). The degree of response elicited by the same dose was not the same for each extract, and also the control and induced frequencies of hyperploidy seemed to depend in part on the nature of the fibroblast cultures. One of the two extracts which did not induce a significant increase in hyperploidy was retested on a second recipient and appeared to give a mild response (subject 18). Extract from one subject was cytotoxic (subject 16).

In order to test the specificity of the reaction, autogeneic lymphocyte extracts were tested, and the results were compared with results obtained when the same extracts were tested simultaneously on allogeneic fibroblasts (Table 3). There were two of seven extracts from "normal" subjects that showed slight responses (subjects 10 and 14). However, none of the seven extracts tested showed an effect on autogeneic fibroblasts near the order

Table 1. HYPERPLOIDY EFFECT OF LYMPHOCYTE EXTRACT FROM PATIENTS WITH "AUTOIMMUNE" DISORDERS ON ALLOGENEIC FIBROBLASTS

Donor No.* (lymphocyte extract)	Recipient No. (fibroblast† culture)	No. of transfers at time of examination	Hyperploidy (per cent) Extract dose (×10⁶ lymphocytes) 0	1	2	4	Endoreduplication (per cent) Extract dose (×10⁶ lymphocytes) 0	1	2	4

* Diagnoses: 2 and 17, see Tables 1 and 2; 22 and 27, normal male infants; 23, 37-year-old female with H.T. (mother of D.S. patient) 3 months after thyroidectomy; 24, adult female with breast tumour; 25 and 26, normal adult males.
† All fibroblasts obtained from skin biopsies.

of magnitude seen when the same extract was tested on allogeneic fibroblasts. The means of the distributions of the two groups are significantly different at the 0·01 level (Wilcoxin two-sample test; see ref. 13). There were two other autogeneic cases that did, however, give substantial increases (on an order of magnitude similar to the allogeneic experiments), but both of these were "abnormal". One was an *XO/XX* mosaic with Hashimoto's thyroiditis (subject 5) and the other was a patient with a history of chronic intermittent undefined severe dermatitis and extensive autogeneic skin grafting (subject 7). The fibroblasts in this one patient were obtained from gingival tissue while the patient was undergoing therapy for periodontal disease.

Finally, as a control, the effect of extracts prepared from fibroblasts was investigated (Table 4). Although these extracts may induce slight responses, the effect of fibroblast extracts from "normal" donors on fibroblast mitoses is smaller than that induced by lymphocyte extracts and there does not seem to be a clear cut dose response. The means of the distributions of the lymphocyte extract results and fibroblast extract results are significantly different at the 0·05 level[13].

These results demonstrate that lymphocyte extracts can produce significant, dose related, increases in the number of hyperploid and endoreduplicated mitoses in allogeneic fibroblasts *in vitro*. The failure to obtain similar results when fibroblast as opposed to lymphocyte extracts were tested suggests that the effect may be specific for certain cells such as the lymphocyte. Moreover, the results obtained when lymphocyte extracts were tested autogeneically were significantly different from the results obtained allogeneically, suggesting that the reaction may at least in part involve self-recognizing mechanisms.

The mechanism producing the hyperploidy is unknown. Polyploidy and endoreduplication have been observed under a variety of conditions[14] including the addition of β-mercaptopyruvate to lymphocytes in culture[15] and ageing of long-term tissue culture[16]. However, no matter what the precipitating event may be, the actual mechanism probably involves either fusion of cells or errors in chromosomal distribution. It is of interest that Ohno has recently demonstrated tetraploidy arising from fusion of coisogenic cells when lymphocytes from animals reciprocally sensitized against each other by skin grafting are mixed together in culture[17]. Cell fusion may also be induced *in vitro* by animal viruses[18]. However, even if the hyperploidy we observed resulted entirely from cell fusion, it is not unreasonable to suggest that the resultant tetraploidy would set the stage for the recovery of a whole range of aneuploid cells. Apart from the observed effect on hyperploidy, there is also a clear-cut effect of allogeneic extract on endoreduplication. This effect indicates that at least some of the hyperploidy may result from errors in chromosomal distribution.

Discussions of the relevance of these results to the clinical chromosomal abnormalities are highly speculative. Before the *in vitro* data can be related to this problem, the active principle will need to be identified through cell fractionization procedures and perhaps also through the application of immunological techniques.

This work was supported in part by grants from the U.S. Public Health Service and the National Science Foundation, and was undertaken during the tenure of a U.S. Public Health Service post-doctoral fellowship (P. J. F.). We thank Mrs. B. Burt and Mrs. L. Steinmann for their technical assistance.

DEOXYRIBONUCLEIC ACID CONTENT OF MITOTIC NUCLEI OF TWO MOUSE TUMOURS

By DR. E. L. ALPEN and M. E. JOHNSTON
U.S. Naval Radiological Defense Laboratory, San Francisco

CYTOPHOTOMETRIC estimation of the deoxyribonucleic acid content of various cell systems has generally revealed a common coefficient of variation of about 15 per cent for diploid (2*N*) nuclei[1], but with few exceptions it has been technically difficult to estimate the DNA content of mitotic (4*N*) nuclei because of the gross inhomogeneity of the DNA. It has been usual to attribute the variability in DNA content found in studies of diploid DNA contents to instrumental and technical errors, and to assume that the content of cellular DNA is constant in

accordance with the generally accepted hypothesis chromosome complement of a nucleus is identified uniform and constant amount of DNA. Recently we ha reported that mitotic nuclei of dog erythroid bone marrow have a coefficient of variation again in the region of 15 per cent[2]. In addition, we have found DNA contents in excess of $4N$ for some non-mitotic nuclei of this presumably non-hyperdiploid cell system. Such observations prompt one to question the validity of the measurement systems.

A new cytophotometric instrument for two wave-length spectrophotometry of cells has recently been developed[3]. This photometer, using the model dye droplet system suggested by Pollister and Ornstein[4], can perform measurements such that the standard error of estimate of droplet dye content derived from the regression of dye content against droplet volume is less than 1 per cent (0·8 per cent). Because the development of the two wave-length method[5,6] and the improvement of electronic and optical devices have permitted refinements not previously available, we have attempted to define the limits of reliability of our system, and at the same time provide basic information on the DNA content of mitotic nuclei. Here we are reporting results obtained with this instrument on two mouse tumour systems, one an ascitic tumour and the other an *in vitro* culture of a leukaemic cell line.

Table 1. RELATIVE DNA CONTENT OF MITOTIC NUCLEI IN TUMOUR *BP*-8 FEULGEN STAIN

Nuclei measured	*N*	Relative DNA content	Standard deviation	Coefficient of variation (per cent)
Prophase to anaphase	45	125·0	6·4	5·1
Telophase (measured together)	20	124·9	6·5	5·2
Telophase (sum of daughters)	20	122·0	7·1	5·8
1/2 Telophase	40	61·1	4·1	6·7
			Mean	5·7

Table 2. RELATIVE DNA CONTENT OF NUCLEI OF CELLS *L*5178*Y* FEULGEN STAIN

Nuclei measured	*N*	Relative DNA content	Standard deviation	Coefficient of variation (per cent)
Prophase to anaphase	110	125·1	7·5	6·0
Telophase (measured together)	22	124·1	7·5	6·0
Telophase (sum of daughters)	19	125·1	8·6	6·9
1/2 Telophase	38	62·7	4·6	7·3
"2*N* cells"	67	61·2	3·6	6·0
			Mean	6·5

The mouse ascitic tumour cell, *BP*-8, was collected from a 7-day old transfer, and a thin smear prepared, air dried, and fixed in formalin-ethanol. The *in vitro* culture of leukaemic cells, *L*5178*Y*, was collected from a log-phase culture 48 h after transfer, and a thin smear prepared and fixed in the same fashion as the *BP*-8. All slides were stained by a modified Feulgen procedure[7]. A standard hydrolysis time of 12 min was used. Each stained slide was mounted on the microspectrophotometer with high viscosity immersion oil ($N_D^{25°C} = 1{\cdot}5150$) on both objective and condenser. Measurements were made by the standard two wave-length method and optical densities converted to relative DNA content from a ready reference table machine-computed and printed from Mendelsohn's[8] adaptations of Patau's[6] formulation. Each nucleus or mitotic figure was measured in duplicate, and all measurements were made on a single slide preparation.

In Tables 1 and 2 are shown the results for measurement of mitotic nuclei of both cell lines. Analysis of variance indicated no systematic difference among prophase, metaphase, anaphase or telophase nuclei for either cell-line. The measurements for the first three of these morphological groups were then pooled. However, values for telophase nuclei were retained in a separate grouping as their characteristics made it possible to measure their relative content of DNA by two independent methods. On one hand, the pair of daughter nuclei may be measured as a single unit to provide an estimate of $4N$ relative DNA content. On the other hand, the two daughter nuclei may be measured separately. In the latter case, the $4N$ value can be obtained by summing the values for pairs of nuclei ("sum of daughters"), or by computing the mean $2N$ value from the individual values and doubling the result.

The mean values for the relative DNA content of mitotic nuclei by the three independent measures, that is, prophase to anaphase nuclei, telophase nuclei, and sums of parts of telophase nuclei, differ by less than 1 per cent with the exception of the "sum of daughters" telophase measurements in tumour *BP*-8. This mean is significantly different ($P < 0{\cdot}01$) from the mean for whole mitotic nuclei, but we feel the discrepancy may be due to failure to measure small chromatin bridges that occasionally exist in the telophase pairs. When the cell line *L*5178*Y* was measured, great care was taken to exclude such cells, and no significant difference among means was discovered. In addition to mitotic measurements, we have estimated the content of DNA in *L*5178*Y* cells judged to be $2N$ by morphological criteria (Table 2). It is obviously difficult to choose by morphology alone those cells which have not yet commenced DNA synthesis. However, plotting a distribution histogram of several hundred non-mitotic cells reveals a modal group at the same relative DNA content. The frequency histogram for "$2N$ cells" and for mitoses of *L*5179*Y* is shown in Fig. 1. The mean of the $2N$ group is 61·2 relative DNA units, slightly less than the $2N$ amount estimated by measurement of mitotic cells (−1 per cent), but this small difference cannot be assigned any real significance because of the selection procedures for the cells.

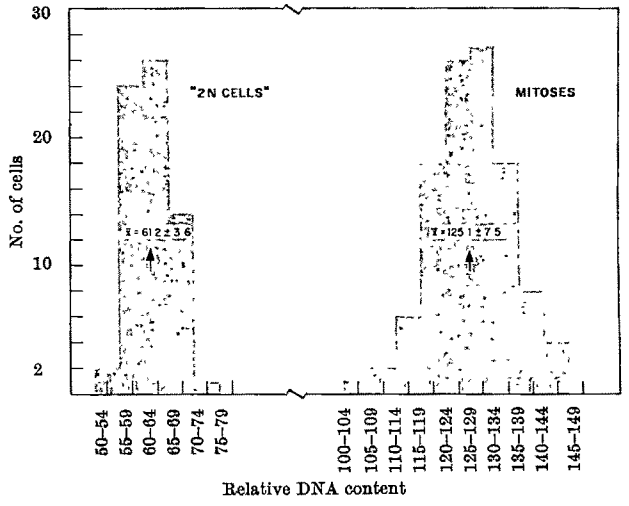

Fig. 1. Frequency histogram for cells of *L*5178*Y*

These measurements simultaneously provided a very rigorous test of the adequacy of the two wave-length correction for chromophore inhomogeneity and of the constancy of DNA content of mitotic nuclei in these cell lines. The coefficient of variation for the mitotic nuclei measured here is about 6·0 per cent. Duplicate measurements of the same cell consistently gave values differing by no more than 1 per cent—a value consistent with that found for error that could be assigned to instrumental causes as determined in tests with the dye droplet model system previously mentioned[4]. Two independent estimates of the telophase content of DNA made by measurement of telophase nuclei as a whole and also as the sum of two parts enable us to estimate

Table 3. ANALYSIS OF RELATIVE DNA CONTENT FOR TELOPHASE NUCLEI COMPARISON OF PAIRED OBSERVATIONS

Cell line	No. of pairs	Mean of paired differences (relative DNA content)	Coefficient of variation (per cent)
BP-8	20	−1·9*	5·9
L5178Y	19	+0·4	4·2

* Significantly different from zero ($P < 0.01$).

those errors attributable to instrumentation and those resulting from the failure of the two wave-length computational method to correct for grossly inhomogeneous distribution of chromophore. The data for the two independent measurements are analysed (Table 3) by computing the paired differences for each pair of nuclei measured by the two methods. The coefficients of variation of the differences for the two cell lines are 4·2 per cent and 5·9 per cent. Because the overall coefficient of variation is of the same order of magnitude (5·7–6·5 per cent), it is possible to assign most of the variability seen to instrumental and mathematical errors inherent in two wave-length microspectrophotometry.

Analysis of goodness of fit to a normal or log-normal distribution for DNA content of mitotic figures in both cell lines demonstrated that the normal distribution best described the data rather than the log-normal distribution as suggested by Garcia[1].

The "constancy" hypothesis has been most clearly restated by Walker and Richards[9]. They stipulate that constancy is applicable at the chromosome level, that is to say, the content of DNA is constant in an individual chromosome and thus also constant in a chromosome set providing that DNA synthesis is complete and that there is no variation in chromosome number. Departure from the constancy hypothesis such as that reported by Lison and Valerie[10] must be supported by evidence that the data are not the result of significant methodological errors. As we have also reported findings[2] of variability in DNA which are not consistent with the constancy hypothesis, albeit in a population of erythroid cells where variability might be more expected, it is incumbent on us to demonstrate the validity of our methodology. For this purpose, we have chosen mitotic cells of two tumours and have shown that the Feulgen method combined with two-wave-length spectrometry is capable of measuring nuclear DNA with an overall coefficient of variation of 5·6 per cent. Furthermore, there was no evidence for alteration in the content of DNA with increasing progress through the stages of mitosis, as analysis of variance of the content of DNA for the morphologically identifiable mitotic stages indicates no systematic variation.

Of equal significance are the results which we obtained for measurement of telophase nuclei by two independent methods: measurement of the whole telophase pair, and measurement of the two daughter nuclei independently. By analysis of these data we have shown that the sum of errors assignable to the instrumental technique plus failure of the two wave-length method to correct completely for chromophore inhomogeneity is of the order of 4–6 per cent. The value of 4 per cent probably represents the best estimates of these errors, as improvements in our manipulative techniques successfully removed a constant negative bias seen when the two measurements were made on telophase nuclei of *BP*-8.

In the light of these findings, it is possible to reaffirm that the stoichiometric relationship of the Feulgen method for measurement of the DNA content of nuclei of at least these two cell lines has a precision of less than 1 per cent. Certainly, these data indicate that the DNA content of mitotic nuclei of these two cell lines rigorously meet the criteria of constancy as set forth by Walker and Richards[9]. The data have also been shown to be best described by the usual normal distribution rather than the log-normal distribution suggested by Garcia[1] for human blood cells.

DEOXYRIBONUCLEIC ACID SYNTHESIS TIME OF ERYTHROPOIETIC AND GRANULOPOIETIC CELLS IN HUMAN BEINGS

By P. STRYCKMANS, DR. E. P. CRONKITE, J. FACHE*, T. M. FLIEDNER and J. RAMOS
Medical Research Center, Brookhaven National Laboratory, Upton, New York

THE DNA synthesis time of canine myelocytes has been reported to be about 7 h[1]. This estimate was used to calculate the relative rates of production of granulocytic precursors at different levels of maturation[2,3]. From these calculations, Patt *et al.*[3] proposed that a "myelocyte sink" exists and that in part granulocyte production may be "death controlled". This question was considered by Cronkite[4] in respect of human erythropoiesis and granulopoiesis. When the 7-h canine DNA synthesis time was used to calculate the relative production rate of red and white cells in human bone marrow, it appeared that a "myelocyte sink" and ineffective erythropoiesis was in operation. However, if one used the DNA synthesis time of about 13 h which has been determined experimentally for the human gastrointestinal tract by Lipkin *et al.*[5], the "myelocyte sink" and ineffective erythropoiesis were not evident. Clearly it became necessary to estimate the DNA synthesis time of human haemopoietic precursors in order to resolve this dilemma. Since the experimental determination of DNA synthesis time of haemopoietic precursors necessitates the administration of tritiated thymidine (^{3}HTdr), a substance which may produce genetic and late effects by radiation injury, only patients incapable of procreation and/or with limited expectancies of life have been investigated. In this article the evidence for a DNA synthesis time of about 13–14 h in human haemopoietic precursors will be presented.

Tritiated thymidine (specific activity 1·9 c./mmole) was given intravenously in a dose of 0·1 μc./g of body weight. Bone marrow was aspirated and blood samples taken at intermittent intervals after injection for 10–15 days. Smears of the marrow were made, dried, fixed in absolute methanol, dipped in Eastman '*NTB*-2' liquid emulsion or covered with 'British Kodak *AR*-10' stripping film, and exposed for 30–120 days in a dry atmosphere at 4° C. They were developed in the standard manner and stained by Giemsa's method. The marrow preparations obtained during the first 48 h are the subject of this

article. Granulocytic and erythrocytic mitotic figures were identified, and the progression of cells (whose DNA was labelled) through the mitotic window and the silver grains overlying these mitoses were observed. Corrections for background fog were made by a modification of Stilstrom's technique[6].

Five patients were investigated. One (SUL) had a brain tumour but was haematologically normal. Another, haematologically normal, was a comatose quadriplegic. One (TOW) had polycythaemia vera (PCV) in a compensated steady state and the other two patients had myeloid metaplasia (ST and TO). Bone marrow could not be obtained in the last two patients, but erythrocytic and myelocytic precursors and mitotic figures were present in the blood. In patient TO, 12–73 erythrocytic mitoses and 6–24 granulopoietic mitoses were observed in each sample. In patient ST, 10–62 basophilic erythroblastic mitoses and 25–86 polychromatic erythroblastic mitoses were seen in each sample.

The principles involved in deducing the length of various phases of the generative cycle from the progression through mitosis have already been published[7].

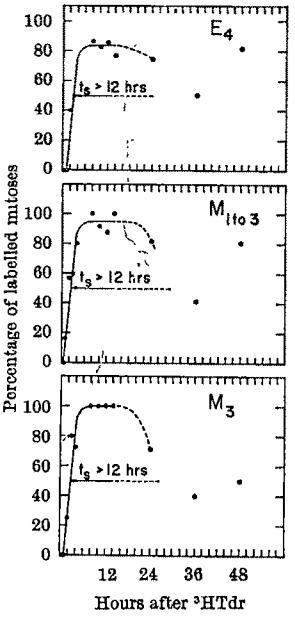

Fig. 1. Progression of labelled erythro- and granulo-poietic precursor cells through mitosis in the bone marrow of a patient with normal haemopoiesis

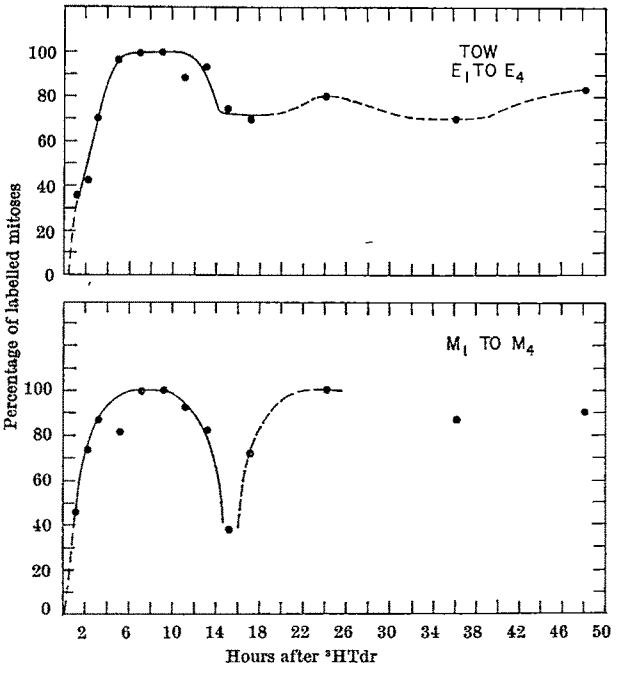

Fig. 2. Progression of labelled erythro- and granulo-poietic precursor cells through mitosis in the bone marrow of a patient with mild polycythaemia vera

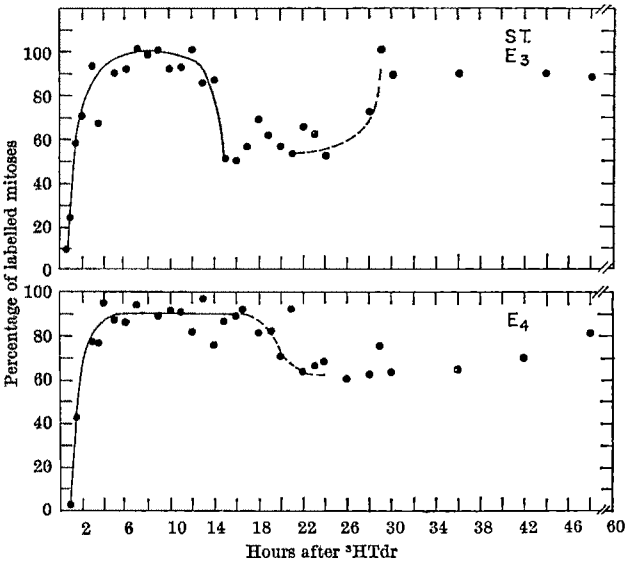

Fig. 3. Progression of labelled erythropoietic precursors through mitosis in the peripheral blood of a patient with myeloid metaplasia

Figs. 1–4 illustrate the progression of the labelled cells through mitosis following the injection of ³HTdr. In Figs. 1 and 2 erythrocytic and granulocytic mitoses are plotted separately. In Fig. 1 (SUL) at the top, progression of the label through mitosis for E_4 (polychromatic normoblasts) is shown. Labelling does not rise above 85 per cent and is maintained for at least 12 h. In the middle, data pooled for M_1–M_3 (myeloblasts through myelocytes) are plotted. Labelling attains about 100 per cent and is maintained for longer than 12 h. At the bottom of Fig. 1, data for only M_3 (large myelocytes) are plotted. Labelling rises to 100 per cent and is maintained for 14 h. Since there were no samples in this patient between 14 and 24 h, a more accurate definition of average DNA synthesis time other than that it is greater than 12 h cannot be made. The progression of labelled erythropoietic precursors through mitosis in the quadriplegic patient indicated an average DNA synthesis time of about 13 h in the pooled erythroblasts. In Fig. 2, progression of labelled cells through mitosis in pooled erythrocytic and granulocytic precursors is shown for a patient with PCV. The minimum synthesis time is about 11 h and the average is about 13 h. At the bottom of Fig. 2, a similar curve is shown for pooled granulocytic precursors. A second wave of labelled mitotic figures is also evident in this case. In Fig. 3, at the top, the progression of labelled basophilic erythroblasts (E_3) through mitosis in the peripheral blood is shown. Bone marrow was not obtainable in this individual because of extensive myelofibrosis. In this patient the minimum time of synthesis is about 12 h and the average about 14 h. In the bottom part of Fig. 3, the progression of labelled polychromatophilic normoblasts (E_4) through mitosis is shown for the same patient. The DNA synthesis time appears longer but cannot be clearly defined. In this instance 100 per cent labelling of E_4 was not observed. Since this may have been due to a failure to detect lightly labelled cells because of inadequate exposure time, a set

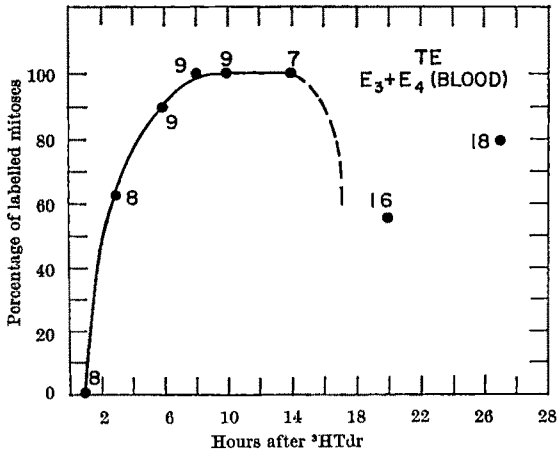

Fig. 4. Progression of labelled erythropoietic precursor cells through mitosis in the peripheral blood of a patient with myeloid metaplasia

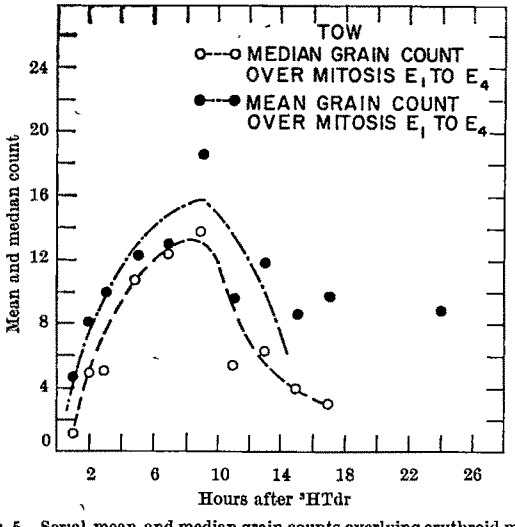

Fig. 5. Serial mean and median grain counts overlying erythroid mitotic figures in the bone marrow of a patient with mild polycythaemia vera after single injection of ^{3}HTdr intravenously

of slides was exposed for 100 days but there was no further increase in the fraction of E_4 labelled. In Fig. 4, another curve of labelled mitoses is shown. This is also based on observations in the peripheral blood. Since mitoses were scarce, the number seen is recorded above each point. DNA synthesis time has a minimum of about 13 h. Data are inadequate to estimate the average synthesis time. In Figs. 5 and 6, the mean and median grain counts overlying mitotic figures are plotted. The variation with time parallels the curves for labelled mitotic figures. The grain count begins with low values, increases to a maximum and subsequently diminishes. The low intensity of labelling over the mitotic figures early and later corresponds to the cells that were just finishing or beginning DNA synthesis respectively during the short time of availability of the ^{3}HTdr. Since they would be in synthesis only for a fraction of the time of availability of the ^{3}HTdr, one would expect lesser incorporation of the label into DNA. Fig. 5 is based on a patient with polycythemia vera. It appears that DNA synthesis time is between the two minima mentioned earlier or about 12–14 h. In Fig. 6, the time between the initial and later minimum suggests a DNA synthesis time between 16 and 18 h for E_4.

In another patient with myeloid metaplasia (St), the labelled mitosis curve for E_4 remained at approximately 100 per cent for more than 20 h without any decrease.

Table 1. PROGRESSION OF LABELLED CELLS FROM E_4 TO E_5 AND THE RELATION BETWEEN NUMBER OF CELLS AND MEAN GRAIN IN E_4 AND E_5 AT SPECIFIED TIME INTERVALS

Time after ^{3}HTdr	Type of cells	No. of cells	No. of grains	No. of labelled cells	Mean grain count
1 h	E_4	125	1,375	51	27
1 h	E_5	360	0	0	0
6 h	E_5	371	362	18	20
12 h	E_5	375	800	49	16·3
18 h	E_5	397	1,433	109	13·1

Table 2. ESTIMATES FOR DNA SYNTHESIS TIME

Patient	Cells	DNA synthesis time Minimum	Average
Normal blood 1	E_4	11	> 12
	M_1–M_3	13	> 13
	M_2	13	> 13
Normal blood 2	E_1–E_4	11	13
Polycythaemia vera	E_1–E_4	11	13
	M_1–M_4	11	13
Myeloid metaplasia	E_3	12	14
	E_4	~16	?
Myeloid metaplasia	E_3 E_4	13	?

Thus an estimate of DNA synthesis time by this method was not practical. However, in Table 1 an analysis of the progression of labelled cells from the dividing E_4 to the non-dividing E_5 (orthochromatic normoblasts) was made as follows. One hour after the intravenous injection of ^{3}HTdr, the labelling index was 51 per cent in E_4 with 1,375 grains overlying 125 E_4 cells. While counting 125 E_4 cells, 360 E_5 were observed which were not labelled. Six and 12 h after ^{3}HTdr injection, the number of grains over the E_5 had increased significantly but had not reached the number found in E_4 at 1 h. However, at 18 h, the number of grains found overlying E_5 equalled the number found over E_4 at 1 h. At 18 h, the number of labelled cells in E_5 was twice that found in E_4 at 1 h and the mean grain count was approximately half. This suggests that the sum of premitotic rest, DNA synthesis, mitosis for

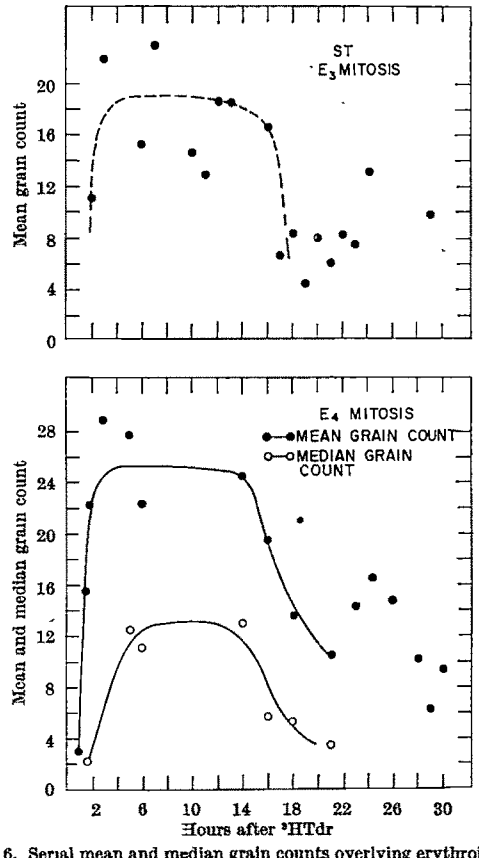

Fig. 6. Serial mean and median grain counts overlying erythroid mitotic figures in the peripheral blood of a patient with myeloid metaplasia

E_4 and maturation to E_5^- is of the order of 18 h in this patient. In Table 2, minimum and average estimates of DNA synthesis are tabulated.

The percentage of labelled mitoses in erythropoiesis did not reach 100 per cent in all instances. Since the increased exposure time of the emulsion did not increase the fraction of mitoses labelled, inadequate exposure time is probably not the cause. Possibly a long premitotic rest (G_2) or maturation of unlabelled cells in parallel with labelled cells to the cellular compartment under investigation are responsible. The increase in the intensity of label over mitotic figures, the plateau and the subsequent decline is probably due to a small fraction of cells at the end and beginning of DNA synthesis which were synthesizing DNA only for a small part of the time when ^{3}HTdr was available and hence are labelled less intensely. Accordingly we believe the time between these minima is approximate to the DNA synthesis time. The computations based on the progression of labelled cells from E_4 to E_5 in patient ST are valid only if E_5 does not lose any label by maturation during the period of observation. Fortunately, the oldest E_5, with partially extruded nuclei, become slightly labelled only 15 h after injection of ^{3}HTdr. This analytical approach shows that the sum of DNA synthesis time, premitotic rest, mitosis and maturation to E_5 is of the order of 18 h. Furthermore, it also suggests that there is only one mitosis of the labelled E_4 cells before they resemble E_5 cells. The apparent generation time of erythroblasts in man is approximately 24 h and cells observed at the beginning of the experiment should thus have divided within 24 h. The cells that were labelled at 1 h should all have divided after an interval equivalent to the sum of DNA synthesis time, premitotic rest and mitosis. In Table 3, the distribution of 437 interphase erythroblasts 1 h after injection are divided into different highly labelled categories. The number of erythroblastic mitoses in the interphase population was recorded during the following 24 h. The distribution of the highly labelled cells is similar in interphase and mitotic cells. This indicates that the most highly labelled cells divided and suggests that there is no radiation inhibition of mitosis by the tritium. The observations have been made on two persons with normal haemopoiesis and three persons with aberrations of haemopoiesis (polycythaemia and myeloid metaplasia) and one cannot be sure that these estimates represent the average for normal human beings. However, the estimates of about 13–14 h for DNA synthesis time in erythropoietic and granulopoietic precursors found in marrow (one normal, one polycythaemic) and in the blood of two patients with myeloid metaplasia are strikingly close to each other and to the estimates of DNA synthesis time in the normal mucosa of the gastrointestinal tract of patients with cancer of the bowel published by Lipkin *et al.*[5]. Furthermore, three different approaches in our investigation (labelled mitosis curves, time between minima in grain counts over mitotic figures, and transport of label from E_4 to E_5) were internally consistent. As it is rare to see a patient with normal haemopoiesis on whom it would be permissible to experiment in this way and who will agree to the multiple bone marrow punctures, it may be a very long time indeed before we will produce more data in our laboratory. However, others are pursuing similar investigations, and the publication of data, scanty as it may be from any one laboratory, appears desirable in order to make it possible ultimately to determine the average values for DNA synthesis on larger numbers of haematologically normal individuals. Clearly DNA synthesis time of erythropoietic and granulopoietic precursors of man in the patients investigated is longer than that of 7 h for canine myelocytes[1–3]. We believe that, until further data are made available, 13–14 h is the best approximation for average DNA synthesis time of erythro- and granulopoietic precursors in man.

Table 3. DISTRIBUTION OF LABELLED INTERPHASE ERYTHROBLASTS 1 H AFTER INJECTION AND OF LABELLED ERYTHROBLASTIC MITOSIS DURING THE ENSUING 24 H

Patient with polycythaemia vera	Number of cells in each grain category				
	> 10G	> 20G	> 30G	> 40G	> 50G
448 mitotic figures the first 24 h after ^{3}HTdr (E_1–E_4)	96	36	6	4	1
437 interphase cells at 1 h after ^{3}HTdr (E_1–E_4)	81	35	5	2	1

To sum up, the DNA synthesis time of erythro- and granulo-poietic precursors of five patients was estimated by observing the movement of labelled cells through mitosis, the time between minima in the grain count over labelled mitotic figures and from an analysis of the movement and intensity of label from a proliferating (E_4) to a non-proliferating (E_5) compartment. We propose that the best present estimate for DNA synthesis time in erythro- and granulo-poietic precursors of man is of the order of 13–14 h.

CHEMICAL TREATMENTS OF STAPHYLOCOCCAL INFECTIONS IN MICE

By DR. IAN M. SMITH, SHIRLEY S. LINDELL, DR. ELIA CH. HAZARD and DR. SERGIO RABINOVICH
Infectious Disease Division, Department of Medicine, College of Medicine and University Hospitals, University of Iowa, Iowa City

PREVIOUS publications by this group of investigators have indicated low values for glucose, protein and cholesterol in the carcases of mice dying of *Staphylococcus aureus* infection. Raised values for inorganic phosphorus and transaminase were also found[1]. Examination of the blood[2] and individual organs[3] of dying mice indicated a low blood sodium and a high alkaline phosphatase. Many, but not all, these derangements occurred in the liver. Unpublished experiments have shown that the blood carbon dioxide combining power in normal animals is 23 μmoles/l. At 1 h, 2 h and 3 h after infection, and at death, it averages 22, 19, 22 and 18 μmoles/l., respectively.

It is important to know if these chemical derangements can provide a clue to the mechanism of death from infection with *Staphylococcus aureus* in mice. We decided to test the importance of these chemical findings by trying to ameliorate or to worsen the derangement by addition or withdrawal of the affected chemicals before or soon after challenge with staphylococci. The results demonstrate that some of these derangements can be altered by subcutaneous treatment with appropriate chemicals to alter significantly the length of life after staphylococcal challenge.

We used the haemolytic coagulase-positive Smith strain of *Staphylococcus aureus*. This strain, originally phage-type 44*A*/42*E* (ref. 4), was isolated from a patient with osteomyelitis. Using the standard phages, however, it is now non-typable. It has been maintained in our

laboratory by regular *in vitro* transfer. Our investigations have shown a reasonably constant number of staphylococci in the bodies of moribund mice regardless of the inoculation route. This work was therefore confined to the use of heavy-dose (0·1 c.c. = 10^9 organisms) intraperitoneal infections. Control infected mice live 270 ± 20 min. The methods have been described previously[5]. The mice used were white Swiss Webster male mice. The animals weighed 20–26 g. Chemicals used for treatment were all given subcutaneously 1 h after challenge unless otherwise stated. All reagents were chemically pure or of U.S.P. standard. Control treatments of equal volume with saline or sucrose were used initially. As they never differed from animals challenged intraperitoneally, they were later abandoned in favour of animals challenged intraperitoneally without subcutaneous treatment as controls.

The analysis of the data was made by comparing the time from challenge until death for ten control animals with the same measurement for ten animals treated. A statistical analysis was also made by the chi-square method. The level of significance used was $P \lesssim 0{\cdot}05$. For the sake of clarity of presentation the tabular material shows the difference in minutes between the control and treated 50 per cent lethal times (*L.T.* 50) with significantly different values starred in the tables.

Glucose given subcutaneously significantly prolongs the life of groups of ten infected mice when compared with groups of ten simultaneously infected control animals. Fasting for 16 h enhances the effect (Table 1). Adrenaline, although it markedly elevated blood sugar, had no effect in six experiments. Insulin was found to have a significantly deleterious effect in most experiments (Table 2). Tolbutamide was tried in twelve experiments, but it rarely had any deleterious effect.

* Blood sugar of normal animals was 189 mg per cent.

Mouse protein (serum, spleen or muscle) or other proteins (human serum or albumin) were without effect in lengthening the life in infected animals.

Injection of crystalline cholesterol failed to raise mouse blood cholesterol, but 1 c.c. of egg yolk daily intraperitoneally for 3 days raised the blood cholesterol from 139 to 1,040 mg per cent, but it failed to delay death from infection.

Phosphate administered as Sorenson's buffer (1/15 M KH_2PO_4 and 1/15 M $Na_2HPO_4.2H_2O$) was a consistently beneficial treatment which prolonged the life of infected mice (Table 3). The components of the buffer were less effective in seventy-two experiments than the combined solution.

Transaminase derived from horse serum (supplied by Sigma Laboratories, St. Louis) was without effect. Sodium given as 2 ml. of normal saline was ineffective and attempts to deplete the animals of sodium with chlorothiazide or mercuhydrin were equally unsuccessful. Alkaline phosphatase from calf intestine or inhibition of alkaline phosphatase by ethylenediamine tetraacetic acid (EDTA) were ineffective treatments.

An investigation of lipid metabolism in mice dying of staphylococcal infection is at present being made. Treatments with castor oil or 'Lipomul' (cotton seed oil with 4 per cent dextrose) were without effect in eighteen experiments, but olive oil (Table 4) probably had some effect.

Treatment with 1/6 M sodium lactate or sodium bicarbonate was consistently beneficial in lengthening the survival time of challenged animals when compared with controls infected simultaneously (Table 5).

The treatment of shock gave confusing results. The mice are profoundly hypothermic (rectal temperature falls from 100° to 65° F before death), but we have been unable to measure blood pressure or cardiac output in these small animals. Urine output ceases soon after challenge. While cortisol in normal doses (5 mg/kg) has no effect on the outcome, if given up to 3 h after challenge in very large doses it will prolong life significantly (Table 6 and ref. 6). Aramine and noradrenaline are without effect or may be deleterious if given 1 h after infection. Wyamine and vasoxyl were also without effect. Warming to 37° C for the duration of the infection is significantly deleterious. Cooling to 4° C was beneficial[7].

Because the mice die after a period of over-activity ending with clonic convulsion[5], it was decided to try to control this over-activity. To this end, treatment with librium and dilantin was used with surprisingly good effects (Table 7). We used amphetamine in an attempt

Table 7. HYPERKINETIC, HYPOKINETIC AND ANTICONVULSANT TREATMENTS OF STAPHYLOCOCCAL INFECTION

10 per cent oxygen, 90 per cent nitrogen with 0·6 atm. pressure for duration of infection	+215*	+241*	+178*

to reverse this effect. This produced well marked excitability in the animals. However, this produced no change in the period of survival. Thorazine was helpful when given before challenge, but deleterious afterwards. The convulsions might either be hypoglycaemic, hypocalcaemic or anoxic. Glucose, as already mentioned, was beneficial, but oxygen and calcium were not. In contrast, low concentration oxygen (10 per cent) or low pressure (0·6 atm.) or both were markedly beneficial (Table 7 and ref. 8).

To sum up, sodium, mercuhydrin, alkaline phosphatase, cholesterol, protein, transaminase, pressor amines, amphetamine and calcium salts had no effect on the time of survival of groups of treated animals compared with untreated control groups when both were challenged with intraperitoneal staphylococci. Insulin had a deleterious effect. Both 10,000 mg/kg doses of glucose and 920 mg/kg doses of phosphate resulted in a 25–35 per cent lengthening in the mean survival time of animals challenged intraperitoneally with *Staphylococcus aureus*. Cortisol in a dose of 250 mg/kg (but not in lower doses), cooling (but not warming) and oxygen deprivation (but not 50 or 100 per cent oxygen treatment) resulted in 16–84 per cent lengthening in the mean survival time of infected animals. Other treatments of value were olive oil and anticonvulsant therapy. This type of approach provides clues to the chemical nature of the death process from *Staphylococcus aureus* in mice.

INHIBITORY ACTION OF THE TESTOSTERONE AND LIVER EXTRACT ON STAPHYLOCOCCAL INFECTIONS IN MICE

By DR. IAN M. SMITH, SHIRLEY S. LINDELL and DR. ELIA CH. HAZARD
Infectious Disease Division, Department of Medicine, College of Medicine and University Hospitals, University of Iowa, Iowa City

THE biochemistry of death from *Staphylococcus aureus* infection has recently been under intensive study[1]. Various chemical constituents of the carcass vary markedly compared with normal values in animals dying of infection. One explanation for these changes could be an exhaustion of normally occurring enzymes or trace elements which could be obtained from suitably treated extracts of normal healthy mouse tissues. In order to explore this possibility we have tested various aqueous extracts of mouse organs and used them for the treatment of severe intraperitoneal infections with staphylococci.

The mice, the staphylococci and the methods used for inoculation and treatment have been described[2]. Organ extracts were made as 1 or 10 per cent w/v aqueous extracts of grinding normal organs with 'Teflon' grinders in suitable volumes of sterile distilled water. The extracts were given subcutaneously 1 h before or 1 h after intraperitoneal challenge with 10^9 *Staphylococcus aureus* cells. All cultures made on these extracts with the exception of 48 h cultures on certain extracts of liver were sterile. With the liver extracts *Escherichia coli* grew in a titre of 10^3 in the 60 per cent suspension within a 24 h period and even later. *E. coli* used in titres of 10^2–10^9 as subcutaneous treatment had no effect on longevity after *S. aureus* challenge. We were unable to detect any deleterious effects of the organ suspensions in normal animals. Controls with normal animals were always run with each experimental test. Liver microsomes were obtained by differential centrifugation in a refrigerated centrifuge using the method of Hogboom, Schneider and Ballade[3]. We consider that microsomes were present in the supernatant and mitochondria in the sediment.

Our results are summarized in Table 1. None of the extracts regularly gave any striking benefit. Liver and testicular extracts had some intermittent beneficial effects but it was only on rare occasions that these results could be confirmed statistically. Adrenal extracts were occasionally helpful.

Table 1. EFFECTS OF ORGAN SUSPENSIONS AS TREATMENT OF STAPHYLOCOCCAL CHALLENGE
(Dose 1–2 c.c. subcutaneously)

	−1 h				+1 h			
	1 per cent		10 per cent		10 per cent		10 per cent

Stomach	—	—	2	+7	—	—	2	−33
Testicle	3	−18	1	+26	—	—	6	−7

We have tried various commercial liver extracts with an extension of the $L.T._{50}$ of from 10–30 min, but again it is not clear that this was not due to the effects of chance. Concentration of the extract (Table 2) produced somewhat better results. There was some evidence that the liver microsomes were more beneficial than the mitochondria (Table 3).

Table 2. EFFECT OF LIVER HOMOGENATE INJECTED SUBCUTANEOUSLY ON TIME OF DEATH AFTER INTRAPERITONEAL *Staphylococcus*

−1	−7	−69*	−23
0	−10	+32	−11
+1	+84*	−30	−23

We have separately tried hyaluronidase and testosterone and we consider these should be the main constituents of testicular extracts. In general, the results with hyaluronidase have not been encouraging. Testosterone, however, has been beneficial (Table 4).

Our results with adrenal extracts led us to a re-examination treatment with cortisone and to raise the dose from 5 mg/kg to 300 mg/kg with excellent results. This investigation will be reported separately[4]. Previously, whatever results have been obtained with organ extracts have been attributed to the fever and leucocytosis which they produce. In the short period available with our animals (about 200 min) we think that this does not occur. We know that in the untreated infection there is a profound hypothermia and leucopenia[1].

Non-specific shock can be induced by protein injections, and this might have some additional effect, but it should be detrimental. Leucocytes, injected subcutaneously as such, have no effect on longevity. If mice are warmed to 37° C they perform poorly after challenge. An environment of 4° C is helpful, and it seems unlikely that fever could be the explanation of the effects of organ extracts[1].

The available information on organ extracts is meagre[5] and it is hard to find it in various published indexes. Weinstein has investigated a variety of compounds of organ extract type in the subcutaneous treatment of an experimental subcutaneous anthrax infection of mice[6]. These include insulin, pineal extract, thymus extract, testosterone, progesterone, thyroxine, pituitary extract, parathyroid extract, gonadotropic hormone, adrenal cortical extract, thyrotropic hormone, growth hormone and prolactin. Certain substances exerted a marked prophylactic effect on infection with anthrax bacilli in mice. These were parathyroid and various extracts of the pituitary gland. Testosterone propionate was moderately protective. Extracts of thymus and pineal gland thyroxine and extracts of the posterior pituitary were also moderately protective. High doses of testosterone were less beneficial than low ones. Doses of 0·12 mg testosterone propionate per mouse per day for 14 days were better than doses of 1·25 mg for the same period.

Nutini and Lynch[7-9] have used extracts of beef brain, spleen, heart and kidney precipitated with 80 per cent alcohol to change an *aureus* virulent form of *staphylococcus* to an *albus* avirulent form. Infections by the subcutaneous, intraperitoneal or intravenous routes in mice could be treated with oral or subcutaneous brain extracts. These extracts, when used prophylactically or therapeutically, reduced the fatality rate in mice from between 76 and 90 per cent to 2 per cent. Spleen was also active, but less markedly so than brain. Heart and kidney had little effect, but liver was deleterious because of its toxicity. We have carried out some experiments with alcoholic extracts of liver and we can report similar toxic responses. Comparisons between their brain extract treatment and penicillin showed the extract to be more active than 2,000 u. penicillin *G* per day per mouse in subcutaneous infections with twenty-four penicillin *G*-resistant strains. It was thought that the extract had a direct effect on the organism, changing it from a virulent to an avirulent form.

Further investigations by Berger *et al.*[10] characterized these extracts as chiefly comprised of aspartic acid, glutamic acid, glycine, alanine, arginine, histidine, amino butyric acid and peptides. The ninhydrin-positive materials were not thought to be responsible for the activity of the extract. Ether extracts of acid fractions of crude brain extract at *p*H 4·5 were very active and therapeutic principle was thought to be the result of unidentified acid substances.

Kroenberg *et al.*[11] have used the coagulate from fresh beef blood. A deproteinized extract from the supernatant of a centrifugation of this coagulate was successfully used to treat a subcutaneous infection of mice with 10^9 *Staphylococcus aureus* or an intraperitoneal infection with 10^8 cells. A 62 per cent protection was found, compared with 21 per cent protection using a crude 80 per cent alcoholic extract of beef blood. They compare this with the effects of an antibiotic called erythrin which was isolated from the blood of various mammals by Zil'ber and Yakobson[12] and was effective both *in vivo* and *in vitro*.

It has been demonstrated that protein synthesis in the *C3H* milk-factor virus mammary tumour is capable of being inhibited by testosterone *in vitro*[13]. It was not effective *in vivo* and it appeared that this could be explained by the rapid metabolism of testosterone by the tumour. Parsons believes that the locus of inhibition of protein synthesis may be at the level of RNA synthesis. This finding may help in the further analysis of our results in the treatment of *Staphylococcus aureus* infections.

It is concluded from these results that a factor or factors may be present in extracts of normal mouse liver adrenal and testicle which is effective in partially protecting mice from the deleterious effects of severe *Staphylococcus aureus* infection. The factor in testicle is probably testosterone. More investigations in this area are needed.

LETTERS TO THE EDITOR

ASTRONOMY

Counts of Radiosources in the *Revised 3 C Catalogue*

IT has been shown that the log N/log S curve for radiosources of high galactic latitude is a straight line with a slope of $-1{\cdot}85 \pm 0{\cdot}05$—at least for fluxes greater than 9×10^{-26} W m^{-2} (c/s)$^{-1}$ at 178 Mc/s (ref. 1). (N is the number of sources brighter than the flux S.)

These radiosources are known to be extra-galactic and to belong to two main classes of objects: the radiogalaxies and the quasi-stellar radiosources (quasars). The radiogalaxies are elliptical giant galaxies; the quasars are stellar objects with very large red-shifts[2-7]. The theoretical log N/log S curves for all the models of the universe, without any evolutionary effect, have a slope of $-1{\cdot}50$ for the larger fluxes and this slope decreases numerically to zero with decreasing flux. Thus the observed slope of $-1{\cdot}85$ for radiosources of high galactic latitude seems to show that there is really some evolutionary effect; if this is so, then the effect must be larger for the quasars than for the radiogalaxies, because on the average the quasars have red-shifts larger than those of the radiogalaxies. To verify this assumption, it is necessary to construct separate log N/log S curves for radiogalaxies and for quasars; to accomplish this a very large number of identifications is required.

A year ago, the number of identifications that had been published was very small, but since then many very accurate radio positions have become available[8-11]. Using these positions, Wyndham[12] and I have made a systematic search to identify any objects in the field of the radiosources in the *Revised 3 C Catalogue*[13] on the *Palomar Sky Survey* prints and plates. We were able to make many positive and tentative new identifications.

The *Revised 3 C Catalogue* provides an extensive survey of the sky north of $\delta = -5°$, for fluxes larger than 9×10^{-26} W m^{-2} (c/s)$^{-1}$, at $\nu = 178$ Mc/s, and it is thus suitable for statistical analysis.

The *Catalogue* deals with 328 sources: (*a*) 32 can be classified as galactic or possibly galactic sources on the basis of positive identifications (Crab Nebula = 3*C* 144, *IC* 434 (H II region) = 3 *C* 147·1, etc.), thermal spectrum, large angular size, radio structure and small galactic latitude; (*b*) 42 sources are probably extragalactic but in absorbed fields near the galactic plane and thus identification is impossible or extremely difficult; (*c*) 254 sources occur in clear fields.

The sources in group *c* were sub-divided into six classes: 100 certain radiogalaxies; 44 possible radiogalaxies; 39 certain quasars; 21 possible quasars; 36 empty fields; 14 non-identified sources. Identification with a galaxy was considered to be 'certain' when there was a very good agreement between optical and radio positions, or when a spectroscopic confirmation had been obtained. It was considered 'possible' when the agreement was not so good. Identification with a quasar was considered 'possible' when a blue star (blue on the *Palomar Sky Survey* prints) was present at the radio position, and 'certain' when spectroscopic or photoelectric confirmation had been obtained[7,14,15]. An 'empty field' was considered to be one where nothing was visible at the limit of the *Palomar Sky Survey* plates ($v \sim 21$) at the radio position. A source was classified as 'not identified' when the radio position was not sufficiently accurate to classify it in any of the previous classes.

It was now possible to construct log N/log S curves for the radiogalaxies and for the quasars. Fig. 1 shows these curves. (*a*) For all the extragalactic sources in the *Revised 3 C Catalogue*, we found the already known slope of $-1{\cdot}85 \pm 0{\cdot}05$. (*b*) For 'certain' and 'possible' radiogalaxies, we found a slope of $-1{\cdot}55 \pm 0{\cdot}05$: this value is normal for objects as near as these galaxies. (*c*) For 'certain' and 'possible' quasars, we found the very large slope of $-2{\cdot}2 \pm 0{\cdot}1$. (*d*) For the quasars, the empty fields and the non-identified sources, we found the same slope, $-2{\cdot}2$.

These findings would seem to indicate that the peculiar slope of $-1{\cdot}85$ found for all the radiosources is due only to the quasars and that almost all the empty fields and 'non-identified' sources are quasars and not radiogalaxies.

Fig. 2 shows the curves for log N/V for 'certain' and 'possible' radiogalaxies and for the 'certain' quasars. (The visual magnitudes (v) of the quasars were measured by Sandage and those of the radiogalaxies either measured by Sandage or estimated on the *Palomar Sky Survey* prints[14,15].) The slope of the log N/V curve for the radiogalaxies at the limiting magnitude $V \sim 21$ is very small and this indicates that the number of galaxies associated with radiosources in the *3 C* revised catalogue, with magnitude greater than 21, is very small. The slope of the log N/V curve for the quasars is much larger and an extrapolation of this curve indicates that a number of quasars has still to be identified. This confirms my suggestion that almost all the 'empty field' and 'non-identified' objects are quasars rather than radiogalaxies.

I thank R. L. Adgie, B. G. Clark, I. I. K. Pauliny-Toth, C. M. Wade, D. S. Heeschen, A. R. Sandage and J. D. Wyndham for enabling me to see their results before publication.

PLANETARY SCIENCE

Potassium–Argon Age of Plutonic Intrusives on Cape Colville Peninsula and Cuvier Island, New Zealand

THIS communication reports the results of potassium–argon age determinations of biotite and hornblende concentrates from each of two quartz diorite samples of the Paritu Pluton (36° 32′ S., 175° 20′ E.), and of plagioclase and biotite from the hornfels on Cuvier Island (36° 26′ S., 175° 46′ E.) from which we were able to obtain an estimate of the age of the Cuvier Plutonics (Table 1).

The field evidence for the age of these intrusions has not been conclusive. The Paritu Tonalite[1] intrudes a basement sedimentary sequence which may have begun in the Permian[1] and extended through to possible Jurassic[2]. Fossil control is poor. These rocks are overlain by terrestrial volcanics which have been subdivided into three successions. Published age estimates range, for the First Period andesites, from Eocene–Miocene[2] to Pliocene–Miocene[3]; for the Second Period (Beeson's Island Volcanics), Miocene[2], Upper Miocene–Pliocene[1], Miocene–Pliocene[3]; for the Third Period, Pliocene[1–3]. Dykes of porphyritic Tertiary andesite are commonly found which cut the Paritu Pluton, which has been classified as pre-Jurassic, but with some Tertiary components, by Frazer and Adams (ref. 2, p. 89); Jurassic to possibly Miocene by Thompson[1]; and Tertiary by Williams (ref. 3, map facing p. 98). D. Skinner, in an unpublished thesis (1962), concluded that the Paritu Pluton was penecontemporaneous with the First and Second Period andesites, which he adjudged to have been erupted during one continuous volcanic episode, ranging from low Pareora (basal Miocene) to low Wanganui (basal Pliocene) in age.

Table 1

Sample No. *GA*	Locality	Mineral	K (per cent)	^{40}Ar (atm. per cent)	^{40}Ar*/^{40}K	Age (m.y.)
1497	Cuvier Island	Biotite	6·70	34·7	0 000958	16 3
		Plagioclase	0·803	60 6	0 000913	15 6
1498	Paritu Quarry	Biotite	7·26	27·2	0 000947	16·1
		Hornblende	0 371	80 3	0·000941	16·0
1499	Darkie Stream	Biotite	5·76	30 3	0 000936	16 0
		Hornblende	0·398	71·3	0 001005	17·1
				79 8	0 001005	17 1

Thompson[1] made the first record of plutonic rocks on Cuvier Island. He suggested that these Cuvier Plutonics are Jurassic to possibly Miocene in age, and that they can probably be correlated with the Paritu tonalite. The occurrence of tourmaline on Cuvier Island and its possible genetic significance have been discussed by Reed[4].

Our Paritu samples come from the type area in the Paritu Quarry[1], 40 ft. from the contact (*GA* 1498), and from Darkie Stream, 500 yd. south-east of Paritu and about 100 yd. from the contact (*GA* 1499). They are essentially fresh quartz-diorite samples, although they both show some signs of uralitization of the hornblende (*GA* 1499, more than 50 per cent; *GA* 1498, somewhat less so), with *GA* 1499 showing sericitization of some feldspars, and presence of epidote. The rock at Paritu is very rich in xenoliths; at Darkie Stream they are much less abundant. The Cuvier Island hornfels sample (*GA* 1497) comes from within 2 ft. of the intrusive contact, sixteen chains south-east of the type area, Scotts Monument. Some sericitization was observed in the plagioclase. Despite this, essentially clean concentrates were obtained for all six minerals analysed

Argon was measured by isotope dilution, using a Reynolds-type mass-spectrometer and a Berkeley-type argon extraction system[5]. Potassium was measured by means of a flame photometer[6,7]. Non-geological sources of error should make up less than 3 per cent of the reported figure (that is, ±0·5 m.y.).

The age concordance between biotite and hornblende from Paritu Quarry suggests that the time of original crystallization has been recorded, for the reason that a later event causing partial argon loss usually results in a hornblende age significantly greater than that of the less-retentive biotite[8]. Biotites from the other two samples suggest that these also are of the same age. The slightly younger age of the Cuvier Island plagioclase relative to the cogenetic biotite can be regarded as confirmatory, as plagioclase feldspars, which often yield reasonable ages, will nevertheless tend to be somewhat less retentive of argon than biotite. The reproducible argon result on the Darkie Stream hornblende suggests that its apparent difference from the biotite result could be real. This could result from: (1) a wrong potassium value (which we doubt, for the potassium replicates (not reported) show their usual "better than 1 per cent" agreement); (2) differential losses of argon from the minerals (the *GA* 1499 hornblende concentrate crystals appear more translucent —that is, have less inclusions—than those of the *GA* 1498 concentrate); (3) the inclusion in the hornblende of a small amount of "initial argon" during crystallization. We cannot distinguish between these alternatives. However, the discrepancy is small, and the samples show no perceptible indications of any alteration which could not be described as deuteric. Thus it seems not unreasonable to conclude that all six ages refer to the same

event, which occurred in mid-Miocene time, probably between 17·1 m.y. and the average, 16·2 m.y., ago. The correlations of Evernden and others[9] suggest that this is equivalent to Late Hemingfordian–early Barstovian on the North American land-mammal sequence. They equate this to the lower Vindobonian of the European sequence, which seems to approximate[10] to the Waiauan Stage in the New Zealand Tertiary succession (Upper Southland Series).

Thus the result confirms the correlation by Thompson[1] of the Cuvier Island Plutonics with the Paritu Tonalite, and also his tentative suggestion that they may be Miocene. On the basis of the allocation of the First and Second Period andesites to the Miocene, our result also lends support to Skinner's suggestion of a close relationship between the plutonic activity and these earlier periods of major andesitic volcanicity.

We thank I. H. Ingram for performing the argon extractions, and H. Berry for help with the mineral purifications.

Determination of Trace Amounts of Cobalt in Sea-water after Enrichment with Solid Manganese Dioxide

FEW results are available on the occurrence of trace amounts of cobalt in sea-water. Noddack and Noddack[1] and Black and Mitchell[2] reported obtaining the values 0·1 μg cobalt/kg and less than 0·3 μg cobalt/l., using emission spectrometry. Ishibashi[3] obtained a value of 0·4–0·7 μg cobalt/l. by spectrophotometry. With improved spectrophotometry, Weiss and Reed[4] and Thompson and Laevastu[5] found values of 0·038 μg cobalt/l. and 0·2–0·3 μg cobalt/l. respectively.

Since a fairly specific and sensitive reagent, nitroso *R* salt, has been widely used for the spectrophotometric estimation of cobalt, it seems that the key to the analysis of trace amounts of cobalt in sea-water is to enrich that element from its sea-water concentration to a concentration suited to the sensitivity of nitroso *R* salt reagent. The method of co-precipitation of cobalt with ferric hydroxide, followed by dithizon extraction used by Ishibashi[3] is inadequate for the recovery of cobalt in sea-water within the range of *p*H in which the bulk of the precipitation of magnesium carbonate and hydroxide can be avoided. The procedure used by Weiss and Reed[4], in which cobalt was directly co-crystallized with α-nitroso-β-naphthol from sea-water, is not practical because of the long after-treatment, involving the decomposition of relatively large quantities of organic reagent, ion-exchange purification and other steps. Thompson and Laevastu[5] utilized carbonate precipitation of naturally occurring magnesium for the recovery of cobalt, but this results in a troublesome filtration procedure. It seems that none of these procedures is practicable for use as a routine method. On the other hand, solid manganese dioxide was used successfully by Yamagata and Iwashima[6] to enrich in a sea-water medium various radionuclides which occur in reactor coolants. They obtained almost complete recovery of manganese-54, cobalt-60 and zinc-65, among others. However, they used 70 g granular manganese dioxide for 20 l. of sea-water, that is, 3·5 g/l. of water. This quantity of manganese dioxide is certainly too great for the purpose of trace analysis of cobalt.

We have attempted to apply the principle of the procedure proposed by Yamagata and Iwashima to the trace analysis of cobalt in sea-water, reducing the quantity of manganese dioxide to minimize the possible contamination and interference caused by excessive amounts of that substance. Experiments using cobalt-60 as tracer showed that as little as 10 mg/l. of manganese dioxide in sea-water can effectively recover trace quantities of cobalt (compare Table 1). The cobalt recovered on solid manganese dioxide can be eluted by less than 50 ml. of 8 M nitric acid. By filtering the elutant through a 'Millipore' filter, a clear solution for cobalt analysis can easily be obtained. This solution can be subjected to the normal procedures for trace analysis of cobalt, that is, the extraction of the α-nitroso-β-naphthol complex and spectrophotometry with nitroso *R* salt[7].

Table 1. RECOVERY AND ANALYSIS OF COBALT DELIBERATELY ADDED TO SEA-WATER

Medium	Cobalt added (μg)	Manganese dioxide (mg)	Cobalt recovered with manganese dioxide (per cent)	Cobalt found* (μg)	Error (per cent)
1 0 l. sea-water	1·0	10·0	90·8	0 92	− 8
,,	2 0	10 5	88·8	2·19	+10
,,	3 0	9·9	91 0	2·54	−15
,,	4 0	10·9	94·3	3·56	−11
,,	5·0	10 0	81·7	4 27	−15
,,	10 0	10 2	84·1	9·31	− 7
,,	Blank	9 8	–	0 46†	–

* Corrected for blank and recovery.
† Reagent blank plus cobalt content of sea-water used.

One possible disadvantage of this enrichment procedure is that small amounts of manganese dioxide might dissolve in the course of the acid treatment. We showed that the presence of 1 mg of manganous ion had a negligible effect on the spectrophotometry of cobalt, while the presence of 10 mg had a definite effect. However, it was shown through tracer experiments with manganese-54 that the quantity of dissolved manganese found after treatment with acid was less than 1 per cent of the total added, and after extraction with α-nitroso-β-naphthol, the contamination of manganese in the final solution was less than 0·5 per cent of the dissolved manganese, a harmless amount.

The main advantages of this enrichment procedure are its speed and simplicity, which make it suitable for use on board ship with the minimum possible contamination. Manganese dioxide, practically free from cobalt, can be prepared by the oxidation of manganous ions in strong nitric acid with potassium bromate. The main source of the reagent blank in the spectrophotometric procedure was the concentrated nitric acid used, which contained up to 0·3 μg cobalt/100 ml.

Table 1 shows the results of experiments carried out on a standard series of water samples, to which known amounts of cobalt had been added, to ascertain the recovery of added cobalt on manganese dioxide and the accuracy of cobalt analyses. In order to measure the percentage recovery 0·1–0·2 μc. of cobalt-60 (~0·001 μg cobalt) was added to each sample. As can be seen from Table 1, the percentage recovery of cobalt ranges from 80 to 95 per cent in these conditions. The error in the determination of cobalt in the 1–10 μg range is expected to be less than ± 20 per cent, although the values obtained tend to be lower than 100 per cent. Table 2 shows the results of the determination of cobalt in a sea-water sample taken from a station located 2 km

Table 2. ANALYSIS OF COBALT IN SEA-WATER

Sample	Chlorinity (per cent)	Manganese dioxide added (mg)	Overall recovery (per cent)	Cobalt found (μg)	Cobalt content (μg/l.)
20 l. filtered sea-water	20 87	200	79 3	1·82	0 091
Analysis of the 'Millipore' filter used for filtration of 20 l. sea-water	–	–	88 8	0 06	0 003

south-west of Monaco in June 1965. In this case also 0·2 μc. of cobalt-60 was added immediately after filtration through an *HA*-type 'Millipore' filter. After the addition of manganese dioxide the sea-water was left to stand for 15 h with stirring.

From these results it is estimated that the content of soluble cobalt in sea-water is of the order of 0·1 μg cobalt/l. and that of particulate cobalt of the order of less than 0·01 μg/l., although the percentage error of the latter was estimated to be much higher than that of the former. Details of the procedures and the results obtained will be presented in greater detail elsewhere.

Oxygen Isotopic Composition of Phosphate from Shells of some Living Crustaceans

RECENTLY one of us[1] reported some results of measurements of the oxygen isotopic composition of phosphate from shells of living marine organisms. Four of the specimens measured were crabs and from the results obtained it was inferred that biological fractionation effects are involved in the process of precipitation of the calcium phosphate of crab shells. It was important to have better information of the behaviour of crabs in this regard in view of the possible utilization of fossil specimens for palaeotemperature measurements on phosphates. For this reason, some crabs were grown under controlled temperature conditions. Some ten specimens of *Carcinides maenas* Rath. (*Carcinus maenas*) were maintained in a thermostatic bath with a continuous inflow of sea water. The reasons for this were: (*a*) to maintain the oxygen isotopic composition of the water at a constant value it is essential to reduce the effects of evaporation; (*b*) that it is necessary to provide a continuous supply of sea water just in case crabs precipitate (at least partially) their calcium phosphate directly from sea water.

The oxygen isotopic composition of the sea water was measured weekly on average samples obtained from daily collections of about 20 c.c. The results covering the period from 1 month before exuviation to 1 month after exuviation give an average oxygen isotopic composition of + 0·6 parts per mil versus standard mean ocean water (SMOW). One standard deviation equals ± 0·1 per mil.

The temperature of the water bath was 25° C and over the whole period it did not vary by more than ± 0·5° C. Such a fluctuation can be considered to be negligible considering the continuous inflow of sea water and the fact that the standard error of the measurements of phosphate δ's, calculated on about 150 measurements, was ± 0·18 per mil which corresponds to about ± 1° C.

The crabs were kept at 25° C some months in advance of moulting in order to ascertain that all the biochemical processes preceding exuviation (principally the major portion of skeletal resorption[2]) occurred at such a temperature.

Because the time which is necessary for the mineralization of the newly formed exoskeleton is not well known, the crabs were kept for various periods in the thermostatic bath after their moulting. In the case of two specimens measured about 2 weeks after exuviation, only traces of calcium phosphate could be detected. Three specimens measured about 5 weeks after exuviation had a phosphate (III) ion content of about 2·0 per cent.

The oxygen isotopic composition of the phosphate of these three specimens was measured according to an earlier technique[1]. The results obtained are expressed in the δ terminology as deviations in per mil of the ratio of oxygen-18 : oxygen-16 in the sample from that in the standard:

$$\delta = 1{,}000 \left(\frac{^{18}O/^{16}O \text{ sample} - ^{18}O/^{16}O \text{ standard}}{^{18}O/^{16}O \text{ standard}} \right)$$

values of δ are given in Table 1.

Table 1

	$\delta^{18}O$ (PO_4^{3-}) vs. CO_2-*PDB*-1	$\delta^{18}O$ (PO_4^{3-}) vs. SMOW
Carcinides maenas No 1	−20 39	+19 68
Carcinides maenas No 2	−20·21	+19·87
Carcinides maenas No 3	−20 50	+19 57

The tentative equation calculated for the relationship between temperature and phosphate δ (ref. 3) is:

$$t = -90{\cdot}0 - 4{\cdot}8\,(\delta_p - \delta_w) \qquad (1)$$

where t is the growth temperature, δ_p is the oxygen isotopic composition of the phosphate and δ_w is the oxygen isotopic composition of carbon dioxide equilibrated isotopically at 25·2° C with the environmental water both measured against the same mass spectrometer standard gas. From this equation the phosphate δ corresponding to a temperature of 25° C with a water δ of + 0·6 (versus SMOW—all the δ's are given here versus SMOW unless specified otherwise) is + 16·60. The average δ from these results is + 19·70. The value is much more positive than would be expected; it can be concluded that, at least in the case considered of the species *Carcinides maenas*, there must be some biological fractionation effect. This effect could be determined, for example, by the processes of partial resorption of the shell material before exuviation and the following redeposition in the newly formed shell.

On the other hand, it seems probable that biological fractionation effects also occur in other crustaceans. In fact we have also obtained measurements for two Mediterranean specimens of *Squilla mantis* and one specimen of *Munida* sp. from deep waters off Florida. In *Squilla mantis* the temperature range is about 13°–23° C and the corresponding phosphate δ's from equation 1 should be (water δ = 0·0) between + 18·7 and + 16·4. In *Munida* sp. (depth about 570 m, growth temperature 7·1 ± 0·1° C) the phosphate δ should be about + 19·9 (water δ = 0·0). The results obtained are given in Table 2.

Assuming a δ value of + 1·0 for Mediterranean water (measured) and a δ value of + 0·6 for *Munida* environmental water (calculated from salinity data from the area) the phosphate δ's are still more positive than they should be. The difference between the two specimens of *Squilla* could be ascribed to different periods of moulting. Also if the number of samples measured is quite small one could conclude that: (*a*) the oxygen isotopic composition of the calcium phosphate of the shell of *Carcinides maenas* (and probably other crabs) is more positive than would be expected on the basis of the equation calculated

Table 2

	$\delta^{18}O$ (PO_4^{3-}) versus CO_2-*PDB*-1	$\delta^{18}O$ (PO_4^{3-}) versus SMOW
Squilla mantis No. 1	−17·50	+22·69
Squilla mantis No. 2	−19 10	+21·02
Munida sp.	−17·44	+22 75

from the results obtained from various marine animals; (*b*) this is also the case for other crustaceans—there seems to be a general tendency toward positive values determined (with some evidence) by biological fractionation effects.

We thank Dr. C. Emiliani for supplying *Munida* samples and S. Nuti for his valuable technical help.

Fossil Ice Wedges in Hampshire

THREE large fossil ice wedges have been discovered in a coastal section exposed at Highcliffe in Hampshire (*M.R.* 215931). They are to be found within the Plateau Gravel in the uppermost part of the cliff at about 100′ *O.D.* Here 2·4 m of gravels rest on Barton Beds, at this point consisting of an impermeable glauconitic clay. On top of the gravels is an uneven layer of brown loam up to 80 cm thick.

The gravels are made up of sub-angular pebbles and smaller chips and flakes of flint; some derived Eocene material, particularly rounded and blackened small pebbles; and quartz and silica sand. There is some differentiation within the gravels, with a lower horizon of coarser stratified material which stands out slightly from the cliff, and thin seams and lenses of finer material incorporated into the gravels above. Two samples taken from the coarser gravel had median grain sizes of 7 mm and 9 mm; they were not well sorted and were strongly skewed towards the finer sediments. A sample from a pinched out lense of finer material, which was some 3 m long with a maximum depth of 20 cm, had a median grain size of 0·35 mm, and consisted largely of medium and coarse sand with patinated chips of flint.

The loam is a structureless deposit, strong brown in colour (Munsell colour 7·5 *YR* 5/6, dry). A layer about 20 cm deep at the surface is weathered to a dark brown (7·5 *YR* 3/2). Four samples taken from the loam had median grain sizes of 14–57μ, but while this falls within the size range characteristic of loess deposits, the samples were not, in fact, well sorted (Trask sorting coefficients from 0·16–0·33), and more closely resembled flood loams. Small pebbles are incorporated into the deposit. Analogous loams may also be found within several New Forest valleys adjacent to the streams along the valley bottoms.

The wedges appear as 'V'-shaped forms of disturbed gravel, often with pebbles inclined vertically, which extend down into the horizontally bedded gravels, and in one case to the top of the clay which is slightly arched up. There is no surface indication of the features on the ground, possibly because the area has been developed as a car park, although there may well have been none. The pattern of the wedges in plan cannot be established; however, they do extend as wedges back into the cliff. They are particularly noticeable because the material within them is partially bleached to a pale brown (10 *YR* 6/3) as compared with the reddish or strong brown of the local material (7·5 *YR* 5/6 or 6/8), although this, too, is also bleached in parts. This is probably because percolating water has found an easy passage down the disturbed gravel[1].

Two of the wedges are almost vertical; the other is inclined with a disturbed area near where it disappears behind scree at about 2 m. The deepest wedge reaches 3 m to the Barton Clay; all three vary from 0·9 m to 1·2 m in width near the top, tapering downwards.

The material fill at first glance appears to be no different from the local gravel, except for the pebble alignment and colour. However, mechanical analysis of samples from one of the wedges reveals that it has a higher proportion of both coarser and finer fragments than the local gravels; median grain size is 14 mm; but 7 per cent is finer than 2 mm (compared with less than 1 per cent), and 43 per cent is more than 16 mm (compared with about 25 per cent). There is no distinctive element from the overlying loam within the wedge. The most likely explanation for all this is that the wedge was an open feature filled from above by fine dust and larger pebbles before the deposition of the loam. Some form of surface depression still existed at that time, however, because the loam thickens immediately over the wedge where the coarser infill does not quite rise to the level of the gravel on either side. Thus, the former existence of an open crack is shown by the nature of the infill, the aligned pebbles and by the thickening of the loam. In two of the wedges there is distortion of the bedded gravels on either side, suggesting ice growth. However, this is not generally marked.

These features are consistent with those of true ice wedges[2], and in size they are closely comparable with those found near Cambridge[3] and in Yorkshire[1]. A number of opinions have been put forward concerning the climatic requirements for the formation of wedges. Corbel[4] suggested that in Alaska they formed under cold continental conditions with little plant cover and low annual precipitation, with a summer maximum, and no considerable snow cover or moisture in winter. He postulated a mean temperature in the warmest month of 10° C, a January–February temperature of −10° to −20° C; Péwé[6] put forward a mean annual temperature of −6° to −8° C persistent for several years.

In the face of these opinions, it may at least be concluded that the fossil ice wedges were formed under a cold continental climate. Temperatures were low enough for permafrost. The wedges may date from the last (Weichsel) glaciation, or conceivably from the Gipping glaciation, as the ground is almost level and may have suffered little disturbance since then. An earlier date is unlikely because the gravels which here form a terrace feature can be correlated with the Goodwood–Slindon raised beach[7], itself assigned to the previous interglacial.

This work was carried out during the tenure of a Nature Conservancy Research studentship at the University of Southampton.

An Unusually Radioactive Fossil Fish from Thurso, Scotland

THE results obtained by Diggle and Saxon[1] on a *Homosteus* plate from Clardon Haven, Thurso, do not, as they suggest, differ in any significant way from those published previously by Atkin and myself[2]. We showed that "whereas both uranium and thorium form organic complexes or compounds with hydrocarbon, only uranium is fixed by bone apatite". This means that a radioactive fish plate without much associated hydrocarbon would have a higher ratio of uranium : thorium than one with abundant hydrocarbon. Thus if the plate studied by Diggle and Saxon was mainly composed of bone apatite

the bulk of the radioactivity would be attributable to uranium.

PHYSICS

Quarks and Cosmology

RECENTLY, Zeldovic *et al.*[1] have described several important astrophysical aspects of quarks. In this communication I shall make some suggestions as to the part that quarks may play in cosmology. Although these ideas are now necessarily speculative, their potential importance seems to warrant at least a brief discussion at this time. A particularly attractive possibility is that a low observed abundance[2,3] of quarks may impose much more stringent limits on the anisotropy of the universe than can be obtained from investigations of radio and quasi-stellar objects.

It seems reasonable to assume that at cosmical densities greater than nuclear densities, and temperatures greater than the quark mass (in units where $c = k = 1$), quarks would be in equilibrium with baryons and consequently would be the dominant form of matter. From these initial conditions, we suppose that the universe expands and two-body reactions between quarks and diquarks produce baryons and mesons. If the baryon mass defect with respect to its component quarks is large, it is possible to ascribe the primeval radiation field to quark combination. If this is not so, then it appears necessary to assume an initial universe comprised of quarks and of radiation in equilibrium with pair-produced particles.

If quark combination is responsible for the radiation field, the required quark mass may be estimated. For example, in the simplest case in which all the cold primordial quarks combine yielding an equilibrium temperature T_q, the present total baryon number density, N_0, and the present radiation temperature T_0, the quark mass would be about $1{\cdot}5 \times 10^{-12}\ T_0^2 T_q / N_0$ GeV. Recent observations[4–8] tend to support a present background radiation temperature[9–11] of about 3 °K. The present total baryon number density is thought to be $N_0 = 10^{-6}$ cm^{-3} (ref. 12) with an uncertainty of about an order of magnitude. For these values and $T_q = 10^{15}$ °K*, the necessary mass is $M_q \approx 4{\cdot}5 \times 10^{10}$ GeV. Although this mass, of the order of that of the most energetic cosmic rays, is very much greater than what is usually considered reasonable for quarks, there is no evidence against the existence of such massive particles.

If quarks did not produce the primeval radiation, Zeldovic *et al.* have shown that their fusion in a homogeneous, isotropic Friedman model would give a present quark concentration in the range $10^{-19} < C_q < 10^{-10}$. Though the uncertainties are large, it is important that even the upper limit implies $C_q \ll 1$, in agreement with available observations. In a homogeneous, anisotropic universe which initially expands from a two-surface[12], it is possible to carry out a similar simple calculation. If such a universe is radiation dominated, we have $T \sim t^{-1/3}$ for the relation between temperature and time, as contrasted with $T \sim t^{-1/2}$ for the isotropic expansion. We assume the total number of primordial quarks to be three times the present number of baryons, and assume, following Zeldovic *et al.*, that quarks combine by way of two-body collisions with an effective cross-section σ (where, for the temperature region of interest, $\langle \sigma v \rangle \approx$ constant). Then the condition for the time-scale of quark combination to be less than or equal to the time-scale for expansion and cooling requires that:

$$\langle \sigma v \rangle \geq 2 \times 10^{-30} \frac{T_0^3 \sqrt{t_a}}{N_0} \text{ cm}^3 \text{ sec}^{-1} \qquad (1)$$

Here v is the quark velocity, and t_a is the time for which the universe preserves its anisotropy. If the primordial quarks also combine to form mesons, the numerical factor in equation 1 could be decreased somewhat. The most uncertain quantity in equation 1 is $\langle \sigma v \rangle$, which eventually should be measured or estimated theoretically. The relation between $\langle \sigma v \rangle$ and the time-scale of anisotropy is plotted in Fig. 1 for several values of T_0^3/N_0 corresponding to $T_0 = 3{\cdot}2$ °K; $N_0 = 10^{-5}$, 10^{-6} and 10^{-7} cm^{-3}. Knowledge of the effective cross-section and velocity, $\langle \sigma v \rangle$, N_0 and T_0 then provides an upper limit on the anisotropy time-scale t_a. If the time-scale of anisotropy were longer than this limit, the rate of cooling would be so rapid that quarks would not have time to combine; their present concentration would be $C_q \approx 1$.

The cross-section for quark production from proton–proton scattering in the statistical model is estimated to be 3×10^{-28} cm^2 for 3 GeV quarks[14]. It decreases very rapidly with increasing quark mass. If this value is typical of the range of cross-sections for quark interactions and is taken as an approximate upper limit to σ for quark combination, then for $v \approx c$, $\langle \sigma v \rangle \approx 10^{-17}$ cm^3 sec^{-1}. This may be compared with $\langle \sigma v \rangle = 7 \times 10^{-20}$ cm^3 sec^{-1} for the formation of helium[13]. From Fig. 1, this puts a very approximate upper limit of 10^{10} sec on t_a. Even allowing for the considerable uncertainty of $\langle \sigma v \rangle$, this suggests that t_a is many times less than the present age ($\approx 4{\cdot}5 \times 10^{17}$ sec) of the universe.

If the universe has always been isotropic during its expansion, a similar calculation shows that $\langle \sigma v \rangle_{\text{isotropic}} \geq 3 \times 10^{-21}\ T_0^3 / N_0 T_q$. For $T_0 = 3{\cdot}2$ °K, $T_q = 10^{13}$ °K, and $N_0 = 10^{-6}$ cm^{-3}, this gives $\langle \sigma v \rangle_{\text{isotropic}} \geq 10^{-26}$ cm^3 sec^{-1}.

The effect of anisotropy (and indeed the effect of any mechanism, such as a scalar field[10], which increases the early rate of expansion) is complementary to its later effect on the evolution of a hydrogen universe. Hawking and Tayler[13] have pointed out that a moderate amount of anisotropy substantially decreases the primeval helium concentration below that predicted by the α–β–γ theory[11]. However, observations do not appear inconsistent with a primeval helium concentration of zero[15]. At present, therefore, the helium calculation can only provide a lower limit to the anisotropy.

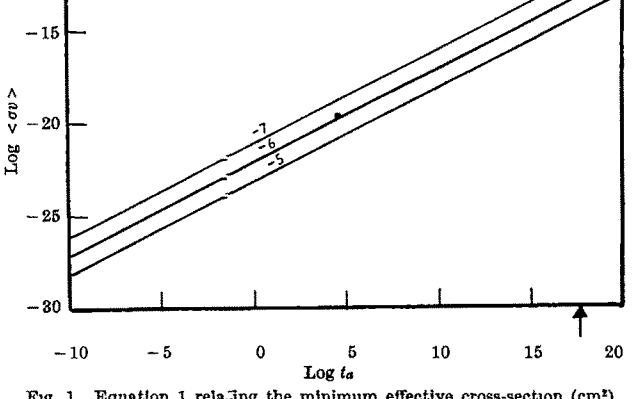

Fig. 1. Equation 1 relating the minimum effective cross-section (cm^2) and velocity (cm sec^{-1}) for quark combination to occur to the time-scale, t_a (sec), for anisotropy. The lines −7, −6, and −5 are for $T_0 = 3{\cdot}2$ °K and for densities $N_0 = 10^{-7}$, 10^{-6} and 10^{-5}. An arrow indicates the approximate present age of the universe

* This temperature is obtained by assuming that the quarks combine when the cosmic density becomes less than the nuclear density of 10^{38} cm^{-3}. Whether the reaction time scale is sufficiently short for this actually to occur depends on the totally unknown cross-sections for extremely massive particles.

It is also important to note another aspect of this model. At the very high temperatures, $T \gtrsim 10^{13}$ °K, at which these reactions occur, pair production of baryons may increase the density substantially. Under these conditions the Fermi temperature $T_f \approx 10^{-13} T^2 (M_n/M_b)$, where M_n is the neutron and M_b the baryon mass. Thus neutrons will not become degenerate until $T \approx 10^{13}$ °K. If quarks are to combine at this or higher temperatures, the quark-baryon mass defect would have to be sufficiently large to release a Fermi energy of about $10^{-26} T^2 (M_n/M_b)$ GeV. Another effect which may become important at high densities is induced if the effective quark radius is much smaller than that of the baryon. In order to create a space Δv for the newly formed baryon, an amount of energy approximately equal to the work $p\Delta v$ must be liberated, where p is the local pressure. Were the mass defect unable to supply the required energy, quark combination would have to be balanced by processes which reduced the local pressure. For quark masses of the order of a few GeV, this also becomes important at temperatures of about 10^{13} °K and such quarks would not be expected to combine at earlier phases of the expansion, except possibly to form a statistical equilibrium with baryons. At these high temperatures there may also be pair production and annihilation of quarks. Such considerations provide relations between quark mass and temperature, and the resultant time-scales for evolution will also be affected by anisotropy and inhomogeneities.

If quark combination from an initially cold universe is responsible for the radiation field, the effects of degeneracy and pair production are less important. In an oscillating universe, the role of quarks may be to exchange energy between the matter and the radiation field during dense phases. Such an exchange, if irreversible, could lead to a damping of the oscillations. The discovery of quarks and their properties may well provide further constraints on theories of the early stages of an expanding universe.

It is a pleasure to thank Dr. R. J. Tayler, Dr. D. W. Sciama and Dr. S. W. Hawking for helpful advice. This work was done during the tenure of a Fulbright fellowship which I gratefully acknowledge.

THE SOLID STATE

Simultaneous Magneto-optic Recording of Hysteresis Loops from Both Surfaces of a Magnetic Film

MAGNETIZATION reversal processes in thin magnetic films have been extensively investigated in recent years. The usual techniques adopted for the display of hysteresis loops have been based on the use of a pick-up coil to detect dM/dt, as described in detail by Crittenden *et al.*[1,2].

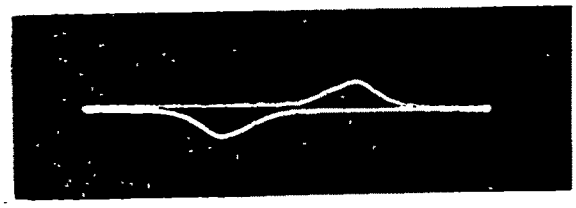

Fig. 1

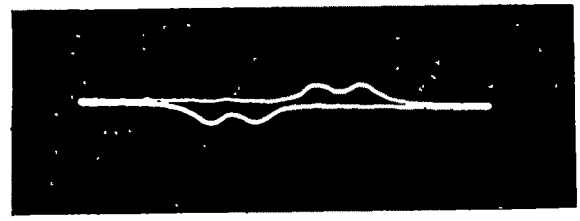

Fig. 2

More recently, use has been made of the magneto-optic effects and, in particular, Green and Thomas[3] have developed a simple technique in which hysteresis loops are obtained using the transverse Kerr effect in the infra-red. With a 50 c/s drive field reversing the magnetization, the intensity changes in the reflected beam are detected by a phototransistor and then amplified.

This technique is being used in investigations of cobalt films in the thickness range 500–4000 Å produced by evaporation on to glass substrates (10–20 Å/sec) and some of the results have already been reported elsewhere[4]. The simplicity of the method has now permitted simultaneous investigations of the magnetization changes occurring at both surfaces of a single film.

In the case of the thinner films (< 2000 Å) the signals detected from each side appear identical. For the thicker films, however, differences are apparent in the signals obtained from each side. This effect first becomes noticeable at a thickness of about 2000 Å and is very pronounced at about 4000 Å. Figs. 1 and 2 show the signals of dM/dt versus drive field taken from the free surface and the substrate surface respectively of a 4000 Å film. It is clear that the reversal process is different at each surface and, furthermore, preliminary results indicate that the effect is dependent on the orientation of the film with respect to the drive field.

Simultaneous recording in this fashion should find useful application in investigations of multiple films.

Synthetic Single Crystals of Graphite

THE formation of Kish graphite in iron/carbon is well known[1], and reports have appeared of the growth of usable single crystals of graphite at 3,200° C in these systems[2]. Such crystals have not had the benefit of formation at a high temperature, so that in order to produce

long-range order they must be annealed. Accordingly, attempts have been made to crystallize graphite from higher melting solvents such as refractory carbides. No graphite was formed when tungsten monocarbide (m.p. 2,785° C) was used as the solvent, but an abundance of large single crystals of graphite was obtained from tantalum monocarbide (m.p. ~3,820° C).

About 40 g of hot pressed (3,100° C; 100 kg cm^{-2}) tantalum monocarbide having a bulk density of 86–91 per cent was placed in a polycrystalline graphite crucible (Morganite *EY9A*) and sealed with a tight-fitting graphite plug. The crucible was insulated with wrappings of graphite felt (National Carbon Co., grade *WDF*) and assembled in a susceptor for use in a developed version of the high-temperature induction furnace described by Moore *et al.*[3]. After outgassing *in vacuo* at 2,000° C and further degassing treatments in 1·6 atm. pressure of argon at temperatures up to 2,900° C, the furnace was filled with fresh argon and the sample rapidly heated to about 3,900° C, at which temperature it was maintained for 9 min. This required a power input of 19–21 kW. At such temperatures the graphite vapour pressure is so high (~0·9 atm.) that more than 60 per cent of the crucible/susceptor evaporated evenly from the outer surface, but of course the molten tantalum carbide was exposed to the same carbon vapour pressure in a closed system.

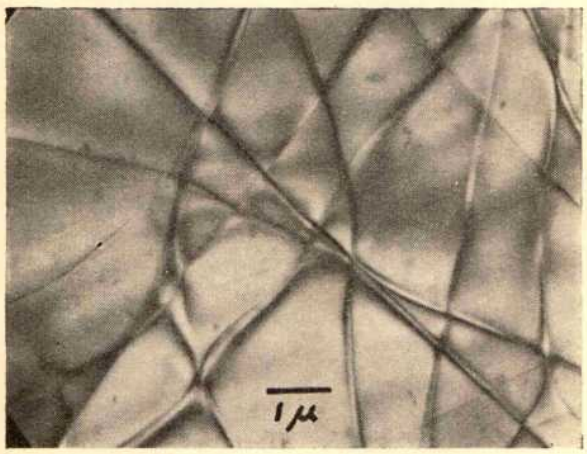

Fig. 1. Electron micrograph of basal plane dislocations in a graphite single crystal grown from solution in molten tantalum carbide. The specks on the plate are artefacts of sample preparation

On examination of the cooled sample, it was found that the molten tantalum carbide had eroded the interior of the crucible at the tantalum carbide/graphite interface only, and that the carbon so removed had reformed as lustrous black flakes up to 8 mm across and 0·3 mm thick, had nucleated at the base of the melt and had grown wholly within it. The interstices were filled with a friable polycrystalline tantalum carbide with the composition $TaC_{0·99}$; this was inferred from the characteristic golden colour and the lattice parameter (4·455 Å)[4]. We therefore conclude that the molten tantalum carbide acted as a transporting solvent.

Examination of the graphite flakes by optical and electron microscopy confirmed that they were single crystals of high quality. Thus characteristic twins contributing equilateral networks of 1·5–2 mm period or basal surfaces were observed to be straight over distanc of 5–8 mm, and specimens taken for electron microsc investigation gave single crystal patterns. The dislocr content, as shown in Fig. 1, is not unduly high. In the extent to which the partial dislocations are dis at nodes implies that this structure is not pinned.

We thank Mr. J. R. White for the electron micrograph.

A Simple Method of Producing Extremely Pure Crystals of α-Silicon Carbide

THIS communication describes a method of preparing colourless, extremely pure crystals of α-silicon carbide by a modified Lely process in a high-vacuum, high-temperature furnace from silicon of a purity sufficient for semi-conductors and pure graphite. The temperature at which the main reaction occurs, in the course of which the crystals are formed, is 2,800° C. The energy gap, determined according to the method devised by Macfarlane and Roberts, is 2·96 eV. Crystal wafers 100–200μ thick with fresh surfaces exhibited a transmission factor of 80–85 per cent at the characteristic wave-length of 2–4μ.

Silicon carbide is an interesting semi-conductor material, not only from the point of view of its physical properties but also because of its use in high-temperature components and possibly also for its applications in lasers. Silicon carbide has been used in the manufacture of non-linear resistors for many years, although the mechanism that gives it the non-linear current-voltage characteristic has hitherto not been fully explained. However, until now it has not been possible commercially to obtain pure, colourless silicon carbide for a satisfactory investigation of its physical properties. For this reason, we set out to produce hexagonal crystals of silicon carbide of high purity; success was finally achieved by means of a modification of the Lely process[1], which will be described here.

From our experience the following are the most important points for any method which is to yield a pure product: (1) Only silicon carbide can be used as the starting material; however, it must be considerably purer than that which can be obtained commercially (but it should be possible to produce it in fairly large quantities without undue expense). (2) The distribution coefficient for impurities varies appreciably with temperature. The higher the temperature of formation in the range investigated (up to 2,900° C), the higher the purity of the final silicon carbide monocrystals for the same starting material. The main difficulty is to attain the high partial pressures for carbon and silicon required to produce the crystals.

To begin with, fine crystalline yellow silicon carbide rting material; however, the production of this by the well known silicon method is a relatively protracted devised another method which ting material with adequate ner. The heating element as a system of chambers pure graphite is used. or quality is placed in heated for a long time lting point of silicon for a brief period gradient between

the directly heated graphite chamber and the silicon, as a result of which molten silicon penetrates the porous graphite where it reacts to form silicon carbide before it can evaporate. Thus the silicon is converted quantitatively into silicon carbide. The entire process takes place in an inert atmosphere. After the excess graphite has been disposed of by combustion, sintered, yellow microcrystalline silicon carbide remains and can be pulverized and used as the starting material for the subsequent process.

As already stated, various experiments indicated that the distribution coefficient of impurities varies appreciably with the temperature, and for this reason it is necessary for the recrystallization of the silicon carbide to occur at as high a temperature as possible. Obviously, because of the high partial pressures required, the ideal would be to use a totally enclosed hollow body of silicon carbide. We endeavoured to realize this by means of the following process. In the first stage a hollow cylinder of graphite is filled with yellow silicon carbide, produced by the foregoing method, and a graphite rod is pushed into the powdered silicon carbide so that it is surrounded by a uniform layer of the material (Fig. 2). If this arrangement is now heated in a high-vacuum furnace to 2,200° C for about 30 min and the graphite is allowed to burn away in air at 800°–900° C for a fairly long period, we are left with a mechanically strong, still slightly porous hollow cylinder of silicon carbide. On account of its porosity, the graphite core can be completely burnt away. The hollow cylinder of silicon carbide is now placed inside another hollow cylinder of graphite and the reaction temperature is increased to about 2,800° C, so that as a result of dissociation and recrystallization the hollow cylinder of silicon carbide becomes much denser. In the hollow space, plane-parallel, colourless crystals—some hexagonal—begin to grow (their dimensions depend on the geometry of the active space). In our experiments the dimensions were a few millimetres in either direction; the thickness varied between 100 and 200μ.

Naturally it is essential to ensure that there is no contamination in any of these processes. The inert gas used

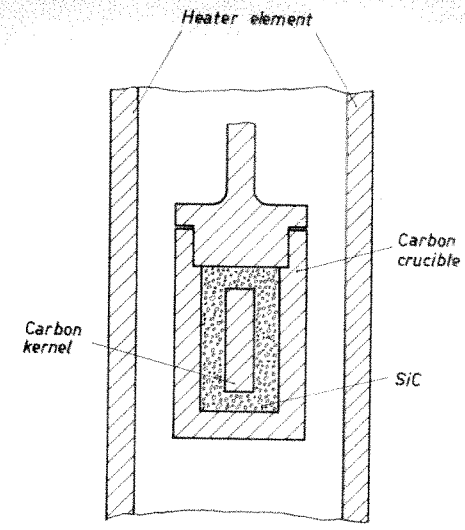

Fig. 2. Arrangement for the production of a cylinder of silicon carbide

was helium—any traces of nitrogen were removed by a calcium trap operated at 700° C, besides the normal methods of purification.

According to Lipson[2], the transmission of light in the range 2–5μ is characteristic of the purity of the material. Our optical measurements confirmed this. For the best wafers the transmission factor in this range amounted to 80–85 per cent for a thickness of 150μ and an untreated surface.

As a means of estimating the purity, we also used the phosphorus content, which can be determined quantitatively with relative ease by measuring the artificial radioactivity (activation analysis) following decomposition of the silicon carbide in a stream of chlorine, or in a sodium carbonate melt. Unfortunately, a number of interesting impurities cannot be considered with this method as their half-lives are extremely short. Although phosphorus is a very specific impurity, the content of this element would seem to offer an appropriate way of determining the general degree of impurity—at least so long as no special measures are taken which affect its content in the compound.

The following are some of the values determined:

Silicon carbide:

(i) commercial, black	1×10^{-2} per cent phosphorus
(ii) commercial, green	3×10^{-4} per cent phosphorus
(iii) starting material, yellow	8×10^{-3} per cent phosphorus
(iv) crystals produced by the method described in this communication	$< 10^{-5}$ per cent phosphorus

Absorption measurements carried out on colourless crystals yielded limits at 3·22–3·25 eV. If these measurements are evaluated with respect to reflexion, according to the methods devised by Macfarlane and Roberts[4], a minimum energy gap of 2·96 eV is obtained. The accuracy of this quantity largely depends on the extent to which the obviously existing long-wave tail can be correctly estimated.

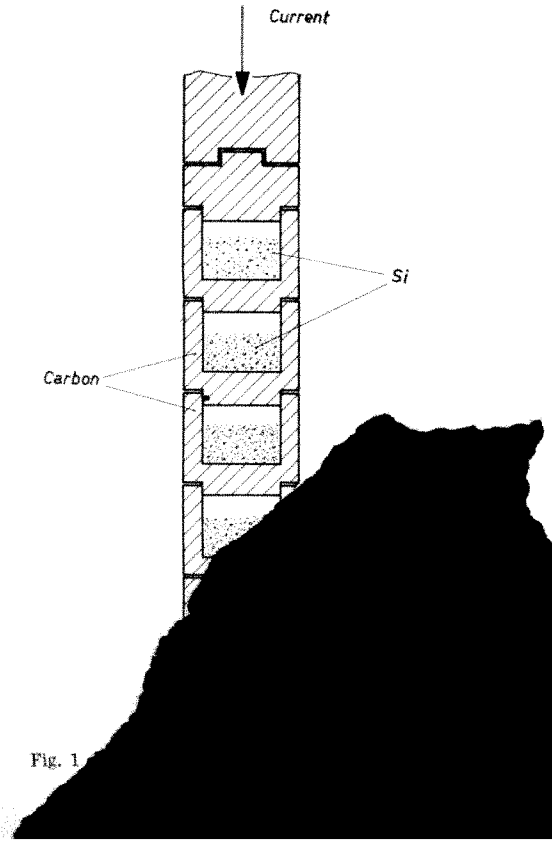

Fig. 1

Internal Friction Effects in Tempered Martensite

It is generally accepted that the high temperature internal friction effects in cold-worked iron containing interstitial atoms and the corresponding effects in martensite are analogous. Both high temperature peaks appear when dislocations and interstitial atoms are present and it is therefore difficult to envisage separate models, although the evidence is mainly comparative and not in any way conclusive.

In the case of the cold-work peak, the dependence on dislocations and interstitial content is easily demonstrated by the fact that the peak is not present when dislocations or carbon or nitrogen atoms are present alone. It is difficult to form martensite with martensitic steels without carbon being present. The most favourable evidence for the similarity between the two effects is to be found in the work of Beaulieu *et al.*[1], who discovered a Koster effect in freshly quenched steels. The Koster effect[2] is found in freshly worked metals where a high internal friction is obtained immediately after working which slowly decays with time. This effect has been attributed to a change in dislocation density and loop-length, although Nowick[3] has suggested that dislocation pinning could also account for this effect. Beaulieu has concluded that the decay of internal friction in martensite arises from the oscillating dislocations collecting point defects and becoming locked. These workers also suggest that the internal friction should pass through a maximum value where the dislocations are moving with the defects.

Gladman and Pickering[4] attempted to investigate the effect of working on the peak height in 0·1 per cent carbon martensitic steel. The martensitic steel was cold-worked and no increase in peak height was obtained. This was attributed to cold-working having little effect on the high dislocation density present in 0·1 per cent carbon martensite. However, the effect of cold-working on the peak height in tempered martensite can be easily investigated. It can be seen in Fig. 1 that tempering reduces the peak height and that a considerable increase in peak damping can be obtained for a very small amount

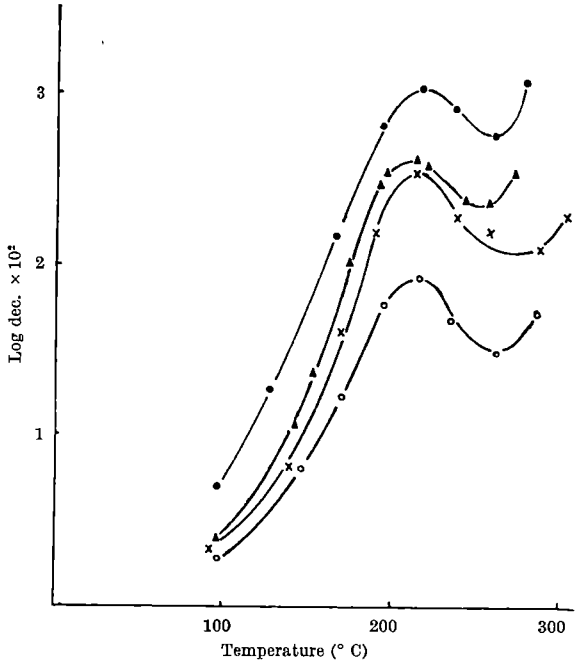

Fig. 1. Effect of tempering and straining 0 4 per cent in tension on the height of the internal friction peak in martensite. Testing frequency, 0 5 c/s. ●, Martensite; ▲, tempered 1 h at 300° C; ×, tempered 1 h at 400° C strained 0 4 per cent; ○, tempered 1 h at 400° C

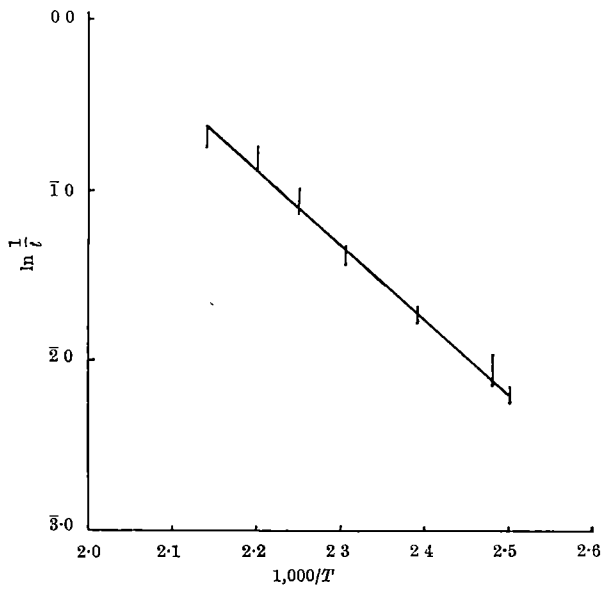

Fig. 2. Arrhenius plot of the natural logarithm of the reciprocal time for complete decay against the reciprocal temperature

of plastic strain. Cottrell[5] has shown that a strain of 10^{-2} can increase the density of mobile dislocations 10^6 times; the strong dependence on cold-working is therefore not surprising.

The connexion between peak height and dislocation population in tempered martensite suggests that, like the cold-worked peak, dislocations are required. The part played by carbon is not easy to establish but some indication can be obtained by performing a Koster-type experiment at elevated temperatures. A 0·4 per cent carbon martensite was prepared by quenching, under cover of argon, from 850° C into brine. Tempering was carried out at 300° C for 1 h before mounting in a torsional pendulum with an optical lever of 3 m. The testing temperature was maintained for 30 min in order to allow temperature gradients within the furnace to be removed before testing. The specimens were deformed *in situ* to a torsional strain of 0·006 radians and the internal friction changes with time followed by determination of the logarithmic decrement over the amplitude range 5 cm down to 1 cm. An Arrhenius plot for the time required for complete decay at various temperatures is shown in Fig. 2, from which an activation energy of $20{\cdot}2 \pm 2$ kcal/mole was obtained. This value is close to the accepted figure of 20·1 kcal/mole for diffusion of carbon in α-iron, and therefore suggests that carbon atoms as well as dislocations play an important part in the high temperature internal friction behaviour of martensite.

These results are interpreted as follows. Immediately on straining, fresh mobile dislocations are formed which are free to bow between their pinning points under the action of the applied stress. The moving dislocation does work against the lattice friction stress. The value of the lattice friction stress controls the extent to which a dislocation will bow, and as a result the damping will decay smoothly with time until the dislocation becomes saturated. Extrapolation of the decay time curves shown in Fig. 2 to zero time, when the dislocation will be moving at the same speed as the carbon atoms, gives a critical temperature of 217° C which agrees with the peak temperature of 215° C. In addition, extrapolation to room temperature shows that the time for complete decay is about 40,000 min. Beaulieu's results show that the damping decayed up to and beyond 20,000 min and an estimate by use of a French curve gives a value for complete decay of 30,000 min. The agreement seems reasonable in view of the difficulty of obtaining the 'end point' experimentally and the inaccuracies inherent in extrapolation. This

indicates that the activation energy for the decay at room temperature is the same as that determined by the present work, and is therefore additional evidence in favour of the pinning model suggested by Beaulieu. However, in my opinion, the high initial internal friction arises from the large area swept out by the moving dislocation. As carbon diffuses to the dislocation and increases the number of pinning points, the total area swept out and thus energy absorbed are smaller than immediately after straining. As a result the damping decreases with time and no maximum on the decay time curve is to be expected, in contrast to that suggested by Beaulieu.

Fatigue Hardening in Face-centred Cubic Metals

A SOFT copper crystal, cycled between constant alternating total strain limits, shows an initially rapid increase in the required alternating peak stresses, $\pm \sigma_P$. At low amplitudes (lives greater than 10^6 cycles) the increase in peak stress becomes very slow after ~ 1 per cent of the expected life. A crystal in this state is said to be fatigue hardened to saturation. Similar behaviour is observed for other face-centred cubic metals of high stacking-fault energy, for example, aluminium or nickel (for a review see ref. 1).

Electron microscopy of thin films from such specimens reveals a high density of edge dislocation dipoles, and few "free" dislocations[2]. This has led Feltner[3] to propose that at saturation the prescribed strain amplitude can be accounted for by flipping of the dipoles between the two stable equilibrium positions for infinite parallel opposite edge dislocations, with much smaller contributions from bowing of segments of free dislocation and of the dipole legs. He also suggests that the shape of the mechanical hysteresis loop at saturation can be accounted for by the observed distribution of dipole widths; narrow dipoles require greater stresses to flip than wide ones.

The following experiment was designed to test Feltner's theory. A 99·994 per cent copper crystal of orientation [112] was cycled in push-pull to saturation with a modified Instron machine reaching an alternating shear stress of $\pm$ 2·76 kg/mm^2. Then a set of hysteresis loops was plotted with a Moseley 'Autograf *XY*' recorder, using an Instron strain gauge extensometer attached to the gauge length. Special precautions ensured that buckling did not affect the readings. Loops were plotted at the saturation stress, and at increasingly lower stress amplitudes down to the limit of the resolution of the system. This procedure did not affect the hysteretic behaviour on returning to saturation stress.

A typical hysteresis loop taken at the saturation stress is shown as *ABCD* in Fig. 1 (the strain axis is horizontal). When the stress amplitude is lowered, the loop shrinks rapidly, as to *EFGH*. Now, from Feltner's theory, it should be possible to construct the loop *EFGH* from *ABCD* as follows. The dipoles which begin to flip on passing from tension to compression at *C* on the curve *BCD* should be the same dipoles that flip on passing *G* on the curve *FGH*. The basic assumption here is that the flipping of these, the widest dipoles, is not influenced by the state of all the other dipoles and whether they have flipped back or not. Thus by simply translating *BCD* bodily to the left, we obtain *B'GH'*; similarly, carrying *DAB* to the right, we obtain *D'EF'*. The 'Feltnerian' loop so constructed, *EF'GH'*, is obviously too soft compared with the observed loop *EFGH*. This means that there must exist internal 'back' stresses at the end of the stroke *DAB* which assist reverse plastic flow during the stroke *BCD*. These back stresses are evidently present to a lesser degree after the stroke *HEF*, so that the curve *FGH* is obtained rather than the predicted *F'GH'*. The origin of the back stresses is not described by the Feltner theory in its present form. However, they may be measured by noting that at *B*, $\sigma_P = \sigma_F + \sigma_B$, where σ_F is a frictional stress opposing flow in either sense, and σ_B is the back stress. Reverse plastic flow on the curve *BCD* begins at $\sigma_R = \sigma_F - \sigma_B$. σ_R may be taken at some arbitrary (small) offset, in order to obtain relative measurements of $\sigma_B = (\sigma_P - \sigma_R)/2$ (see Fig. 1). In this way, a set of values for σ_B can be obtained for a set of immediately preceding peak stresses. Thus the difference between the back stress at *C* after the stroke *DAB* and the back stress at *G* after the stroke *HEF* can be measured. This difference can now be applied to the curve *B'GH'* as a translation downwards along the elastic line *B'G*. If this is done, it is found that *B'GH'* usually fits reasonably well along *FGH*, within experimental error. Similarly, *D'EF'* is moved upwards, and fits along *HEF*. The fact that this construction is satisfactory suggests that there is, approximately at least, a cyclic state which is a function of amplitude, but the metal must be taken around the hysteresis loop at the chosen amplitude a few times in order to wipe out the previous internal stress history. It seems difficult to reconcile this behaviour with a pure dipole flipping model, as the stress field associated with a dipole does not extend much further than one dipole width away. In general, the dipoles appear to be separated more widely than this; further, a rather special grouping of dipoles would be required.

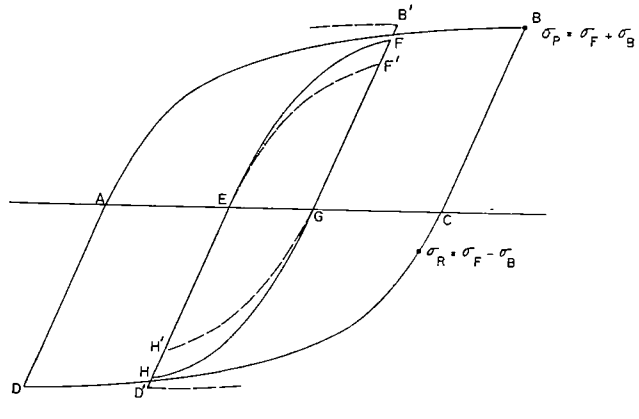

Fig. 1

We suggest that a substantial part of the prescribed strain amplitude does not arise from dipole flipping, but is a result of flow in the soft[4] persistent slip bands which form at saturation[1]. They are associated with a cell structure of dislocation[5]. At high amplitudes (lives less than 10^4 cycles), a similar cell structure fills the crystal, and high internal stresses are observed in corresponding hysteresis loops[6]. This structure appears able to account for the present observations. Dislocations shuttling back and forth between cell walls contribute to the observed strain amplitude; as they pile up at one side σ_B increases; σ_F arises from their tangling with the walls. At σ_R the first dislocations are disentangled from the walls and move back; as they do so, σ_B is reduced.

The problem now is to assess the relative contributions of dipole flipping and cell shuttling to the total strain.

The present experiments are being extended to higher and lower saturation stresses, and correlated with observations of slip. The effects of orientation and temperature have also been measured.

ENGINEERING

Wind Forces and the Proximity of Cooling Towers to Each Other

Gunn and Malik have recently suggested[1] that their results showing the effect of spacing on the drag of an array of spheres in a closed duct provide an explanation for the collapse of the Ferrybridge cooling towers. It is well known that the drag of a grid of bars or a screen in a wind tunnel increases rapidly as the solidity (that is, the blocked area over the total area) increases. The air passes through the grid as a series of jets and, crudely, it can be argued that the velocity in these jets varies as the solidity. Because aerodynamic forces increase as the square of velocity the drag of the grid will go up as the square of the solidity. For an array of spheres the solidity is $\frac{\pi}{4}(1+a)^{-2}$, where a is the gap in diameters between adjacent spheres; Gunn and Malik present results for $a = 1{\cdot}0$, $0{\cdot}5$ and 0. Using this crude theory, over this range one might expect an increase in drag coefficient based on upstream velocity of some sixteen times.

However, Baines and Peterson[2] devised a more exact theory for the drag of grids. They equated $\frac{R}{\rho U^2}$, where R is the force on unit projected area, to $\frac{S}{2(1-S)^2}$, where S is the solidity. The shape of the bars and any Reynolds number effects are ignored. At high Reynolds numbers these effects are likely to be small in comparison with the effect of the wind tunnel blockage. The array of spheres tested by Gunn and Malik was twenty layers deep but because the spacing was small it will be considered as a single grid. Table 1 gives a comparison of the measurements of Gunn and Malik, at their highest Reynolds number of 2×10^3, with those predicted by the method of Baines and Peterson

Table 1

a	S	$\frac{R}{\rho U^2}$ measured	$\frac{S}{2(1-S)^2}$ predicted
0	0·785	7·3	8 5
0 5	0·349	0 25	0 41
1 0	0 197	0 14	0 15

Thus, although Gunn and Malik's results are very interesting, they were to be expected. However, they bear little relation to the forces experienced on an array of cooling towers in an unconstrained airflow: indeed, if their results were relevant to groups of cooling towers, they would also be applicable to building complexes generally, and would imply wind loadings large enough to have caused failure of a great many of our major buildings and structures.

CHEMISTRY

Food from Coal-derived Materials by Microbial Synthesis

THE explosive increase in the world's population has been accompanied by an overall food shortage. New and increased supplies of food, especially high quality protein, are urgently needed. Earlier investigations have described the growth of micro-organisms on paraffins, synthetic liquid fuel ('Kogasin'), and petroleum fractions[1–3]. Recently, it has been found that micro-organisms convert petroleum or petroleum fractions to protein, vitamins, or amino-acids[4–14]. Because coal is a cheap fossil fuel and by far the most abundant source of readily available, fixed carbon, investigations were initiated to determine whether coal could serve as a source of high protein food.

This communication reports some results of an evaluation of a variety of coal-derived materials as growth substrates for micro-organisms. Emphasis was placed on liquid coal-derived fractions because of the possibility of extending the utility of fuels and chemicals from coal conversion processes. In general, we found that yields of growth on several coal-derived materials compared favourably with yields on pure hydrocarbons and on a petroleum-derived fraction.

The yeasts *Candida lipolytica* (strains 409, 409*A*, 409*B*), *C. tropicalis* 410, and six unidentified species of bacteria isolated from soil by enrichment culture were used as test organisms. The basal growth medium (*p*H 7·0) contained 5·0 g ammonium nitrate, 2·5 g potassium monohydrogen phosphate, 1·0 g $MgSO_4 \cdot 7H_2O$, 0·1 g yeast extract per litre of tap water and to this was added, as the major source of carbon and energy, a weighed quantity of one of the substrates described here. Triplicate cultures (50 ml. of medium in 300 ml. Erlenmeyer flasks) were incubated at 30° C for 4–6 days (bacteria) or 6 days (yeasts) on a rotary shaker. The resultant growth was collected on tared solvent resistant membrane filters, washed free of residual substrate with acetone followed by *n*-hexane, and then dried and weighed. Yields were corrected for growth in triplicate controls without added substrate.

The following substrates were tested as major sources of carbon and energy:

Fischer-Tropsch synthetic liquid fuel fractions: FTL (boiling 0°–204° C), FTD (204°–316° C), and FTW (> 316° C) were Bureau of Mines products (iron catalyst); fraction SASOL (C_{11}–C_{20}, mainly C_{12}–C_{18}: 64 per cent paraffins, 33 per cent olefines; both mostly normal) was a product of the South African Coal, Oil, and Gas Corporation.

Low temperature tar fractions: HSF (a "hexane solubles" forerun with about 7 per cent phenols) and HSD (a "hexane solubles" distillate with about 12 per cent phenols) were obtained from the Texas Power and Light Company. These fractions constituted 7 and 46 per cent, respectively, of the primary tar from Rockdale lignite. Passage of fractions HSF and HSD through alumina provided hydroxyl-free fractions HSFφ and HSDφ (infra-red analysis). Paraffin-rich fraction CTP (88 per cent *n*-paraffins-C_8–C_{15}; 12 per cent normal α-olefines, C_{10}–C_{14}) and paraffin,

olefine fraction CTPO (44 per cent *n*-paraffins, C_9–C_{18}; 56 per cent normal α-olefines, C_9–C_{18}) were derived from the neutral oil of low temperature tar by the Bureau of Mines.

Petroleum-derived fraction PET, obtained from an industrial company, consisted of C_9–C_{14} *n*-paraffins. Other substrates tested were three coal acid mixtures (one from anthracite, two from bituminous coal) and an artificial mixture of polynuclear aromatic hydrocarbons found in high temperature coal tar.

The highest yields of growth with yeasts were obtained with *n*-hexadecane as substrate; yields on 1-octadecene were decreased by about one-half (Table 1). Normal paraffin fraction PET (from petroleum) supported growth yields ranging from a low of 244 mg dry weight (*C. tropicalis* 410) to a high of 430 mg dry weight (*C. lipolytica* 409*B*). Fischer–Tropsch fractions FTD (*C. lipolytica* 409*B*), FTW and SASOL (all *Candida* strains) as well as low temperature tar fraction CTPO (*C. lipolytica* 409, 409*A*, 409*B*) supported growth yields within the broad range obtained on fraction PET. The yield of *C. lipolytica* 409*B* on low temperature tar fraction CTPO approached the lower limit of the yield on fraction PET. The crude protein content of *Candida lipolytica* 409*B* grown on Fischer–Tropsch fraction SASOL was 41·1 per cent, which compares favourably with values reported for micro-organisms grown on petroleum hydrocarbons[10–14].

Table 1. GROWTH YIELDS OF YEASTS ON PURE HYDROCARBONS AND FRACTIONS DERIVED FROM COAL OR PETROLEUM

Substrate (carbon source) Fischer–Tropsch	Growth yield (mg/g substrate)[a] *C. lipolytica* 409	*C. lipolytica* 409*A*	*C. lipolytica* 409*B*	*C. tropicalis* 410
FTL	0(1)	0(1)	0(1)	0(1)
FTD	114–134(2)	115–150(2)	243–280(2)	0(1)
FTW	287–306(2)	127–167(2)	329–344(2)	161–200(2)
SASOL	322–326(2)	341–347(2)	348–451(3)	224–261(2)
Low temperature tar				
HSF	0(1)	0(1)	0(1)	0(1)
HSFφ	0(1)	0(1)	0(1)	0(1)
HSD	14(1)	6(1)	0(1)	0(1)
HSDφ[b]	73*–83†(2)	43*–72†(2)	0*–106†(2)	62*–102†(2)
CTPO	113(1)	124(1)	233(1)	205(1)
CTP	259–272(2)	235–276(2)	287–294(2)	208–232(2)
Petroleum				
PET	280–342(3)	306–338(3)	374–430(3)	244–290(3)
Pure hydrocarbons				
1-Octadecene	357(1)	295(1)	244(1)	344(1)
n-Hexadecane	719(1)	628(1)	433(1)	453(1)

[a] Growth yield (mean of growth in triplicate culture vessels) refers to mg of dry cell material synthesized per gram of substrate added. Mean low and high growth yields are given for experiments which were repeated (number of experiments in parentheses).

[b] Growth yield on HSDφ freed of phenols by two (*) or three (†) passes on alumina.

The coal acids and the mixture of polynuclear aromatic hydrocarbons proved inferior nutrients for bacteria; yields of growth in all cases were less than 100 mg dry weight. No significant growth of yeasts could be obtained on the coal acids and the polynuclear aromatics.

These results suggest that, in general, higher yields of growth of yeasts are favoured by substrates (carbon and energy sources) which (*a*) are higher boiling, and thus of higher molecular weight (as shown by yields on FTL, FTD, and FTW); (*b*) contain a high ratio of normal paraffins to olefines (compare yields on *n*-hexadecane with 1-octadecene; PET, CTP, and SASOL with CTPO); and (*c*) are low in phenols or other toxic compounds removed by alumina (compare yields on HSD with HSDφ).

We conclude that paraffin-rich, higher molecular weight fractions derived from low temperature coal tar and from Fischer–Tropsch synthetic liquid fuel compare favourably with a petroleum-derived fraction as substrates for microbial production of food. Coal, therefore, may join petroleum as a potential source of high protein food.

Chemical Synthesis of the Tryptophan Path Intermediate 1-(*o*-Carboxyphenylamino)-1-deoxy-D-ribulose 5-Phosphate

THE Amadori compound 1-(*o*-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate has been shown to be an intermediate of tryptophan biosynthesis in *Aerobacter aerogenes*[1,2] and *Escherichia coli*[3]. In the course of an attempt to synthesize chemically the suggested intermediate, *N*-(5′-phosphoribosyl) anthranilic acid, I found that a compound with the properties and spectral characteristics of the Amadori rearrangement product was formed[4]. The method of synthesis of this compound has not been previously described, as until recently I have not used it in biological systems. The product (synthesized in 1960) has recently been used as a substrate in investigations of indoleglycerolphosphate synthetase in extracts of different micro-organisms. Since 1960 the intermediate, in the form of a sodium salt and another sample in the form of a barium salt, has survived a trip round the world and storage under refrigeration at 4° and −15° C.

The method of synthesis described here relates to the particular sample for which spectra are given and which we used as an enzyme substrate. Smith and Yanofsky[5] have described a synthesis of the intermediate, but in their method a crystalline product was not obtained. The present method is only one of several procedures successfully tried, but no attempt has been made to develop the synthesis fully.

Ribose 5-phosphate barium salt (1 mmole) was dissolved in 1 ml. water. Sodium sulphate (1·1 mmoles) was added and the precipitate of barium sulphate filtered off and washed with 0·25 ml. water. The combined filtrate and washings were added to 2 ml. ethanol with stirring. This resulted in a slight cloudiness. Anthranilic acid (2 mmoles) in 2 ml. ethanol was added and resulted in a rapid clarification of the reaction mixture and a tendency to turn yellow. After stirring for 3 h 10 min the reaction mixture was placed in the refrigerator. The supernatant was decanted and the residual oil triturated with ethanol. The resulting yellow solid was filtered, dried under vacuum. The yield was 150 mg (41 per cent based on ribose 5-phosphate). The product was very hygroscopic. A similar

Table 1. PROPERTIES OF REACTION PRODUCT COMPARED WITH THOSE OF ANTHRANILIC ACID AS DETERMINED ON PAPER CHROMATOGRAMS

Reagent	Reaction product	Anthranilic acid
R_F	0·63 (tailing)	0·86
Ultra-violet light	not fluorescent	blue fluorescence
Alkaline triphenyltetrazolium chloride	Red (positive)	nil
Ammonium molybdate (75°, 15 min)	Blue-green	nil
Phloroglucinol (90°, 2·5 min)	Purple (weak reaction)	nil, yellow on keeping

The reaction with phloroglucinol is somewhat different from that of the non-phosphorylated Amadori compound which gives a green-purple reaction (ref. 2).

product melted at 177–181° C (with violent decomposition).

A sample of the crude product was dissolved in water, then acidified to a *p*H below 2 and chromatographed on Whatman No. 1 paper (solvent, methanol : butanol : benzene : water, 2 : 1 : 1 : 1 by volume) using a descending technique. A comparison between the properties of the product and anthranilic acid is given in Table 1. These properties are as expected for the phosphorylated Amadori intermediate. A comparison with the mobility of the non-phosphorylated form, as found in earlier work[2], indicates a slightly lower mobility for the phosphate. It should be noted that the phosphorylated intermediate does not fluoresce in ultra-violet light. This is in contrast with the non-phosphorylated form which fluoresces blue in a similar manner to anthranilic acid.

Ultra-violet spectral analyses carried out at the time of synthesis have been given previously[4]. The crude product was assumed to be 1-(*o*-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate disodium salt. Weight, spectra and conversion with alkali to anthranilic acid[3] indicated a purity of 60 per cent, with an impurity of 8 per cent anthranilic acid, on molar calculation. Previous experience with glycosylamine derivatives of anthranilic acid has indicated that they can have considerable water, or solvent, of crystallization[2].

For enzyme experiments, a solution of the disodium salt, synthesized in 1960, was made in water. This was acidified with hydrochloric acid to a *p*H below 2·5 and extracted with 2 × 4 ml. ether in order to remove anthranilic acid and the dephosphorylated Amadori compound. The aqueous layer was separated and the remaining traces of ether evaporated off by bubbling a stream of argon through the solution. The *p*H was then adjusted to 5·2. Conversion to anthranilic acid with alkali (*p*H greater than 10, 1·5 h at room temperature) and measurement of the absorption at 307 mμ allowed the concentration of the Amadori compound to be calculated[3]. The spectral characteristics of 1-(*o*-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate have now been calculated (Fig. 1). 0·1 M *tris*-hydrochloric acid buffer, *p*H 7·4, $\varepsilon_{249m\mu}$ 8,100, $\varepsilon_{326m\mu}$ 3,250; *p*H adjusted to less than 2·5 with hydrochloric acid, $\varepsilon_{249m\mu}$ 6,600, $\varepsilon_{343m\mu}$ 3,800 (measured immediately, later falling to extinction similar to *p*H 7·4, because of the keto-enol equilibrium). In water adjusted to *p*H 5·2, $\varepsilon_{248\cdot5m\mu}$ 7,200, $\varepsilon_{336m\mu}$ 3,500.

Because of the cost of ribose 5-phosphate and the suitability of the product for enzyme work, no further chemical investigations were carried out. In an early preparation a barium salt was precipitated with barium acetate. Smith and Yanofsky[5] comment that their attempts at purification, using ion exchange resins, failed. However, taking into account the method of preparation and the likely impurities, the following purification procedure is suggested.

Prepare the sodium salt by the method given here. The likely impurities are anthranilic acid and the non-phosphorylated Amadori compound. These can be removed by acidification and extraction with ether. The aqueous layer will probably contain some ribose 5-phosphate and ribose. If barium acetate is added, the Amadori compound will be precipitated as the barium salt, while barium ribose 5-phosphate and ribose remain soluble. A preliminary preparation indicated that a barium salt of at least 95 per cent purity was obtained. This is not very soluble, but may readily be converted to the soluble sodium salt with sodium sulphate, or presumably with an appropriate ion exchange resin.

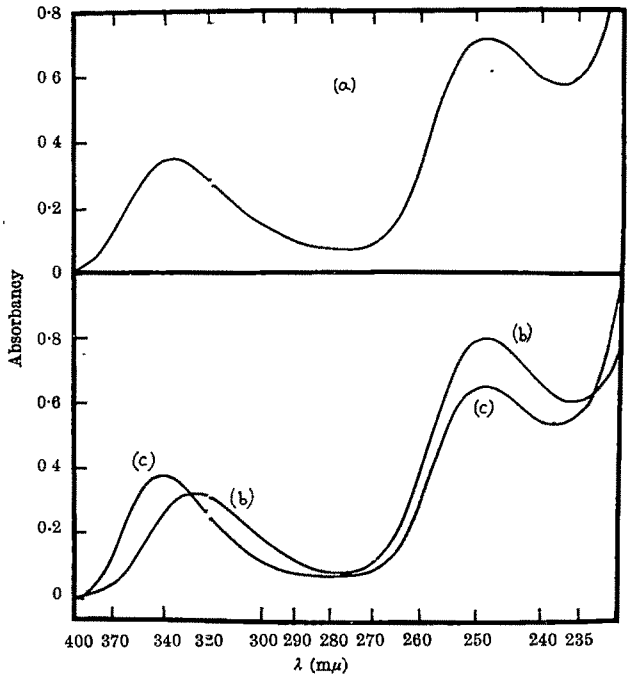

Fig. 1. Spectra of 1-(*o*-carboxyphenylamino)-1-deoxy-D-ribulose 5-phosphate at 10^{-4} M (*a*) in water at *p*H 5·2. (*b*) in 0·1 M *tris*-hydrochloric acid buffer, *p*H 7·4, (*c*) as (*b*) but *p*H adjusted to less than 2·5 with hydrochloric acid and spectrum recorded immediately. The spectral data given by Smith and Yanofsky (ref. 5) suggest that their sample was contaminated with anthranilic acid, but no extinctions or actual spectra were given. The extinctions indicated by the spectra of Doy (ref. 4) were lower than the present ones because that sample on a weight basis was only 55–60 per cent pure with some contamination with anthranilic acid (probably 8 per cent on a molar basis)

Transacylation of Acetyluramil or Acetylthiouramil; formation of Oxazolo(5,4-*d*)pyrimidines

CONDENSED pyrimidine ring compounds have been widely investigated, but relatively little is known of oxazolo-(5,4-*d*)pyrimidines, which have so far been prepared by the cyclization of uramil with acetic anhydride or benzoyl chloride[1,2], of 5-acyl- or 5-aroyl-amino-4-hydroxypyrimidines with phosphorus oxychloride[3–5], or by the Curtius reaction of 4-aminopyrimidine-5-carbohydrazides[6].

In order to obtain 2-methyloxazolo(5,4-*d*)pyrimidines, unsuccessful attempts were made to cyclize acetyluramil (I), m.p. 270–3° C (dec) (acetic acid) (found: carbon, 38·63 per cent; hydrogen, 3·79 per cent. The formula $C_6H_7N_3O_4$ requires: carbon, 38·92 per cent; hydrogen, 3·81 per cent), or its 2-thio analogue (II), m.p. > 300° C (dissolved in 10 per cent sodium hydroxide afterwards acidified with hydrochloric acid. Found: carbon, 33·38 per cent hydrogen, 3·97 per cent. $C_6H_7N_3O_3S{\cdot}H_2O$ requires: carbon, 32·87 per cent; hydrogen, 4·14 per cent), obtainable by the condensation of ethyl acetaminomalonate with urea or thiourea in the presence of sodium ethoxide, with acetyl chloride, acetic anhydride, or phosphorus oxychloride.

On the other hand, the treatment of these compounds with benzoyl chloride gave the cyclized products. Heating (I) in refluxing benzoyl chloride with subsequent dissolution of the reaction mixture in ethanol gave 2-phenyloxazolo (5,4-*d*)pyrimidine-5,7-dione (III), m.p. 282–3° C (dec) (methanol) (found: carbon, 57·49 per cent; hydrogen, 3·00 per cent; nitrogen, 18·36 per cent. $C_{11}H_7N_3O_3$ requires: carbon, 57·64 per cent; hydrogen, 3·08 per cent; nitrogen, 18·34 per cent), λ_{max} 321 mμ (log ε 4·10) in ethanol. Its major infra-red absorptions ('Nujol') were at 1689(*s*), 1639(*w*), 1597(*vw*), 1550(*w*), 1316 (*w*), 1261 (*w*), 1227(*w*) and 1136(*w*) cm^{-1}. However, with large excess of this cyclization reagent, 2-phenyloxazolo(5,4-*d*)-pyrimidine-4,6-dibenzoyl-5,7-dione (IV), m.p. 188–9° (ethyl acetate) (found: carbon, 68·32 per cent; hydrogen, 3·40 per cent. $C_{25}H_{15}N_3O_5$ requires: carbon, 68·65 per cent; hydrogen, 3·64 per cent), λ_{max} 301 mμ (log ε 4·40) with an inflexion at 293 mμ (log ε 4·38) in chloroform was isolated, the major infra-red absorptions ('Nujol') of which were at 1767(*s*), 1631(*s*), 1608(*m*), 1587(*w*), 1550(*w*), 1486(*m*), 1418(*m*), 1325(*m*), 1266(*s*), 1242(*s*), 1181(*m*), 1099(*s*), 1080(*s*), 1060(*s*), 1037(*s*), 1031(*s*), 1015(*s*), 1002(*m*) and 986(*s*) cm^{-1}. Hydrolysis of (IV) with aqueous sodium hydroxide in acetone afforded (III), with m.p. 282° C (dec) (found: carbon, 57·29 per cent; hydrogen, 3·07 per cent).

(I) R=H; R_1=Ac; X=O
(II) R=H; R_1=Ac; X=S
(VIII) R=C_6H_5; R_1=H; X=S
(III) R_2=R_3=H; X=O
(IV) R_2=R_3=C_6H_5CO; X=O
(V) R_2=H, R_3=C_6H_5CO; X=S
(VI) R_2=C_6H_5CO; R_3=H, X=S
(VII) R_2=R_3=H; X=S
(IX) R_2=R_3=C_6H_5; X=S

The ease of formation of (IV) indicates the presence of (III) predominantly as a lactam form. This was confirmed by infra-red spectrum analysis ($\nu_{C=O}$ 1,689 cm^{-1}).

Analogous treatment of (II) with large excess of refluxing benzoyl chloride gave monobenzoylated compound, m.p. 228–9° C (dioxane-*n*-hexane) (found: carbon, 61·48 per cent; hydrogen, 3·09 per cent; nitrogen, 11·86 per cent. $C_{18}H_{11}N_3O_3S$ requires: carbon, 61·89 per cent; hydrogen, 3·15 per cent; nitrogen, 12·03 per cent), λ_{max} 319 mμ (log ε 3·97) with an inflexion at 332 mμ (log 3·87) in dioxane, showing major infra-red absorptions ('Nujol') at 1695(*s*), 1647(*sh*), 1582(*w*), 1553(*w*), 1515(*w*), 1351(*m*), 1318(*w*), 1267(*w*), 1221(*w*), 1205(*m*), and 1176(*w*) cm^{-1}. No absorption was found at about 2,500 cm^{-1}, and this suggested a thiolactam structure for this compound.

Hydrolysis of this compound with aqueous sodium hydroxide in acetone afforded 2-phenyloxazolo(5,4-*d*)-pyrimidine-5-thione-7-one (VII), m.p. 248–9° C (dec) (acetone) (found: carbon, 53·79 per cent; hydrogen, 3·04 per cent. $C_{11}H_7N_3O_2S$ requires: carbon, 53·87 per cent; hydrogen, 2·87 per cent), showing major infra-red frequencies ('Nujol') at 1695(*s*), 1667(*sh*), 1634(*m*), 1613(*w*), 1600(*sh*), 1575(*m*), 1351(*m*), 1230(*s*), and 1106(*s*) cm^{-1}.

These results indicate the occurrence of transacylation of (I) or (II) with a benzoyl group before cyclization to oxazolo(5,4-*d*)pyrimidine ring. This would be caused by the hydrolytic cleavage of an acetyl group, with the subsequent benzoylation of uramil or thiouramil. The labile nature of an acetyl group in acetyluramil was noted by Piloty *et al.*[7].

Nitrosation of 1,3-diphenyl-2-thiobarbituric acid gave its 5-nitroso compound, m.p. 226–8° C (dec) (methanol) (found: carbon, 58·72 per cent; hydrogen, 3·53 per cent. $C_6H_{11}N_3O_3S$ requires: carbon, 59·07 per cent; hydrogen, 3·41 per cent), which was reduced with ammonium sulphide to its 5-amino derivative (VIII), m.p. 190–2° C (dec) (dissolved in 10 per cent sodium hydroxide with subsequent acidification with hydrochloric acid) (found: carbon, 54·98 per cent; hydrogen, 4·94 per cent. $C_{16}H_{13}N_3O_2S{\cdot}2H_2O$ requires: carbon, 55·32 per cent; hydrogen, 4·93 per cent). (VIII) was cyclized with benzoyl chloride to 2,4,6-triphenyloxazolo(5,4-*d*)pyrimidine-5,7-dione (IX), m.p. 264–5° C (dec) (toluene) (found: carbon, 69·46 per cent; hydrogen, 3·78 per cent; sulphur, 8·48 per cent. $C_{23}H_{15}N_3O_2S$ requires: carbon, 69·50 per cent; hydrogen, 3·80 per cent; sulphur, 8·07 per cent), λ_{max} 329 mμ (log ε 4·41) with an inflexion at 341 mμ (log ε 4·22) in chloroform, which showed major infra-red absorption ('Nujol') at 1727(*s*), 1645(*m*), 1597(*w*), 1493(*m*), 1326(*m*), 1297(*w*), and 1250(*s*) cm^{-1}.

Carbonyl stretching vibrations in the cyclization product of (II), and that of (VII), were at the same value (1,695 cm^{-1}). The lower value of this frequency, compared with that in (IX) (1,727 cm^{-1}), are probably due to intermolecular association.

However, no conclusion could be drawn from these and other available data on the structure of the cyclization product of (II), which should be (V) or (VI).

A noteworthy feature of the infra-red spectra of (III), (IV), (V or VI), (VII) and (IX) is the appearance of an absorption, the intensity of which is variable, in the region 1,650–1,630 cm^{-1}. This may be associated with the C=C or C=N valency vibration of the oxazole ring, if the pyrimidine moiety takes the lactam form. An absorption with medium intensity in the region 1,600–1,490 cm^{-1} ((II), 1,567; (VII), 1,575; (IX), 1,493 cm^{-1}) can be attributed to a vibration of the N—C=S group. The shift of this absorption to the lower value in (IX) would be caused by the increased conjugation of nitrogen atoms with phenyl groups, but for (V or VI) no frequency due to this group can be seen in this region. An absorption at about 1,200 cm^{-1} ((II), 1,224; (V or VI), 1,205; (VII), 1,230; (IX), 1,250 cm^{-1}) was correlated with $\nu_{C=S}$.

Proton Microanalysis

A NUMBER of papers have been published[1-5] which demonstrate the use of nuclear reactions induced by charged particles as a tool for the measurement of light element concentrations. This "nuclear analysis" technique differs from conventional activation analysis in that suitable detectors are used to measure promptly the products (particles or radiation) of the reaction rather than the decay products present after the completion of the irradiation. Despite its many advantages, the technique has not become widely known or used. We show here that it is particularly suitable for application to the microanalysis of light elements in a manner which complements the electron probe microanalyser. The use of a small diameter proton beam (for example, 0·010 in. or less) to induce nuclear reactions permits non-destructive measurements to be made, particularly for light elements, which are often difficult to detect by other methods.

The specific object of the particular experiments was the determination of the degree of homogeneity of thin foils of αTi-O alloys prepared for an investigation of the

solid solution region (less than 33 atom per cent oxygen) by electron diffraction methods. A suitable nuclear reaction for the investigation of oxygen concentration is the $^{18}O(p,\alpha)^{15}N$ reaction. Using protons of 0·86 MeV, a dominant resonance is observed in the alpha-particle yield, and the cross-section is sufficiently high to offset the low natural abundance of oxygen-18 (0·2 per cent).

The experiment was carried out using a proton beam from the 3-MeV accelerator at the Physics Division of the Australian Atomic Energy Commission Research Establishment. A simple chamber was used, with the titanium oxide samples mounted on a movable arm controlled from outside the vacuum system. A silicon semi-conductor counter was mounted on a second arm to receive α-particles emitted at 90° to the incident proton beam. A 2·5 mg/cm² aluminium foil in front of the counter absorbed scattered protons but allowed the 3·86 MeV α-particles to penetrate to the detector. The pulse height spectrum observed with a multi-channel analyser is shown in the inset to Fig. 1. A broad peak is observed owing to energy loss by some α-particles as they emerge from the surface of the sample. Most of the α-particles are produced within a distance of 2μ from the surface but a small number are produced at depths up to 5–10μ, and lose considerable energy in the sample. Repeated measurements of the pulse height spectrum for a fixed number of microcoulombs of protons incident on the sample were made to investigate the accuracy and reproducibility of the results. No effects were observed from drifts in the accelerator or measuring equipment or from build-up of contamination on the surface of the sample. However, when a sample of rutile (TiO_2) was used, a slow drop in oxygen concentration with time of bombardment was observed for a current density of 1 m.amp cm⁻². No such change was observed for the other titanium oxides used—a result which is consistent with the differences in thermal conductivity. An inspection of the rutile sample after bombardment showed that it had melted in the region of the beam spot.

For microanalysis, an aperture 0·010 in. in diameter was used to restrict the size of the beam striking the sample, and the total number of counts in the peak region of the alpha spectrum was used as a measure of the oxygen concentration in the region of the beam spot. The results are shown in Fig. 1, plotted against position

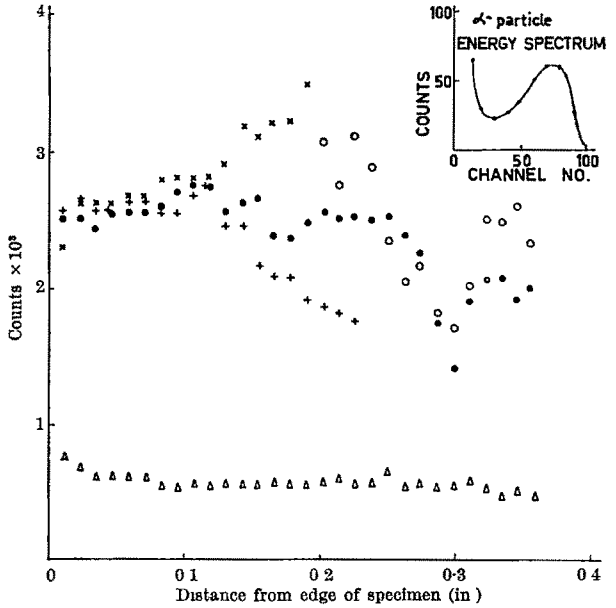

Fig. 1. Oxygen distribution in titanium oxides. 1*a* (●), 15 per cent oxygen by weight with scanning lines 0·15 in. apart; and 1*b* (○), 15 per cent oxygen by weight with scanning lines 0·15 in. apart; 2*a* (×), 12·4 per cent oxygen by weight with scanning line perpendicular to edge; 2*b* (+), 12·4 per cent oxygen by weight with scanning line parallel to edge; 3 (△), 3 per cent oxygen by weight

on the sample for a number of specimens. Using a beam current of 0·2 μamp and a counting time of about 3 min (33 μC), a statistical accuracy of from 2 per cent to 5 per cent was obtained depending on the oxygen concentration. Repeated results obtained by returning to a particular spot on the sample always gave results which agreed within the statistical errors.

Curves 1*a* and 1*b* in Fig. 1 are for two traverses, 0·015 in. apart, across one sample. The dip observed in both traverses occurs for a particular grain which shows an oxygen concentration 30 per cent lower than that of the surrounding material. Curves 2*a* and 2*b* show a relatively smooth change in oxygen concentration and this can be correlated with an observed change in average grain size. Curve 3 shows a uniform oxygen concentration across the surface of the sample.

Some measurements have been made with a 0·004 in. diameter beam spot and it should be possible to reduce this to 0·001 in. Special equipment would be needed to allow measurements for much smaller spot sizes, but such work would be feasible provided care were taken to avoid damage to the sample by high-beam densities.

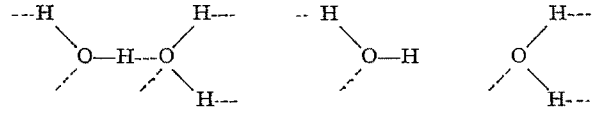
Proton Nuclear Magnetic Relaxation Investigations of Water



A STRUCTURAL model for water represents the liquid as a mobile, imperfect framework with molecular water or waters at defect sites[1]. The framework is connected by hydrogen bonds while the molecules held interstitially are hydrogen bonded neither to each other nor to framework molecules. This communication reports experimental results consistent with this model as provided by an investigation of aqueous proton nuclear magnetic relaxation times.

Relaxation measurements[2] were made on solutions in the *p*H ranges 2–5 and 9–12. T_1 was found to be neither *p*H- nor frequency-dependent and the values at room[3] and elevated temperatures[4] agreed with those reported by others for oxygen-free water. At 26° C and in the *p*H ranges indicated, T_2 was dependent on frequency but not on *p*H. At 60 Mc/s, T_2 was found to be less than T_1, while both were equal at 4·3 Mc/s. Representative measurements at various temperatures in the acidic range and at 60 and 4·3 Mc/s are shown in Table 1. Further data on the *p*H and frequency dependence can be found elsewhere[2].

Table 1. T_1 AND T_2 FOR ACIDIC WATER SOLUTIONS AT VARIOUS TEMPERATURES AND FREQUENCIES

*p*H 2·5, 60 Mc/s			*p*H 1·8, 4·3 Mc/s		
T° C	T_1	T_2	T° C	T_1	T_2
27·7	3·70	3·42	25·5	3·56	3·55
31·1	4·10	3·76	30·5	3·98	—
34·9	4·50	4·13	31·6	—	4·07
41·0	5·22	4·72	37·7	4·60	4·55
46·5	5·72	5·27	46·8	—	5·54
55·5	6·60	6·10	48·0	5·60	—
63·6	7·50	6·90	53·0	6·07	6·10
			60·5	6·85	6·87

In treating the data, we assume that the frequency dependence of T_2 can be traced to effects associated with a chemical shift, δ. The shift is ascribed to the difference in resonance frequency between that for a hydrogen bonded proton and one without this specific interaction. The mean diffusion lifetime[5] for water, however, renders it unlikely that the frequency dependence observed by us could be related to the reorientation of molecules partially involved in hydrogen bonding as represented below:

With this structure, fluctuations result in the breaking of one hydrogen bond (dotted lines) while others are left intact. We require a process, for example, whereby a water molecule is transferred from one state with hydrogen bonds to another without hydrogen bonds. This can best be described as the kinetic process, in the model, for transfer of a water molecule from the framework to an interstitial site. Furthermore, due to the *p*H independence of T_1 and T_2 in the *p*H ranges indicated, water molecules rather than protons are transferred from state to state.

In the limit of fast exchange, T_1 and T_2 can be related to a mean lifetime, τ, by equation 1 (ref. 6).

$$\frac{1}{T_2} - \frac{1}{T_1} = P_A P_B \delta^2 \tau; \tau = 1/(1/\tau_A + 1/\tau_B) \qquad (1)$$

In (1), P_A and P_B are the mole fractions of water in the framework state, A, and the interstitial state, B. Further, $\tau_A/\tau_B = P_A/P_B = K$, for the reaction $B \rightleftarrows A$.

The X-ray investigations of Danford and Levy[7] suggest that P_A is 0·80 and P_B is 0·20 at room temperature. If P_A is taken as 0·68 and P_B as 0·32 at 65° C[1,8], the experimental change in heat capacity can be realized after making a reasonable choice for the heat of vaporization of A, 11 kcal. The chemical shift is not required in evaluating thermo-dynamic constants, but only in order to obtain τ_A and τ_B. δ has been chosen as 10 p.p.m., a factor of two higher than that estimated by Hindman[9]. Values for τ_A and τ_B and enthalpic and enthropic rate and equilibrium constants are shown in Table 2.

Table 2. SUMMARY OF KINETIC AND THERMODYNAMIC CONSTANTS

P_A	0 80†	0 68‡	τ_A†	$5{\cdot}8 \times 10^{-8}$ sec	$\Delta S^+_{A\to B}$†	0 eu
P_B	0 20†	0·32‡	τ_B†	$1{\cdot}4 \times 10^{-8}$ sec	$\Delta S^+_{B\to A}$†	−7 7 eu
ΔS^*	−7·7 eu		$\Delta H^+_{A\to B}$ 7·7 kcal			
ΔH^*	−3·1 kcal		$\Delta H^+_{B\to A}$ 4 6 kcal			

* For the equilibrium, $B \rightleftarrows A$. † At 25°C. ‡ At 65° C.

The process $A \rightleftarrows B$ is a type of self-diffusion in water. The forward rate constant, however, is more than three orders of magnitude slower than that for the self-diffusion process postulated as $A \to A$. Applying first-order rate theory to both processes, the enthalpic term is found to reduce the rate $A \to B$ as compared to $A \to A$[4,5] by somewhat more than two orders of magnitude. The rate $A \to A$ is associated with a positive enthropic term[5], while the enthropic term for $A \to B$ is approximately zero. The latter corresponds to the usual enthropic variation for diffusion processes[10]. The indicated difference in rate constant between that for the processes $A \to A$ and $A \to B$ seems consistent, therefore, with that expected for a self-diffusion process.

The rate constant for $B \to A$ shows a similar consistency. The enthalpic terms for $A \to A$ and $B \to A$ are essentially identical, but the enthropic term for the latter reaction is at least 13 eu more negative than that for the former and indicates the expected restrictions associated with a water molecule joining the framework. Nothing can be said, at present, concerning the process $B \to B$.

Further investigations in this area promise additional information about the effects of solutes and mixed solvents on the properties of water. Temperature investigations, above and below the range presently examined, should also provide interesting data on structural variations.

This work was supported in part by a research grant from the U.S. Public Health Service and in part by a contract between the Division of Biology and Medicine, U.S. Atomic Energy Commission, and the Florida State University.

Criterion of Mechanism based on Optical Rotation and Rearrangement in Alkyl Groups during Formation of Alkyl Halides

THE geometrical and electronic requirements of replacement reactions designated S_N2, S_N1 and S_Ni were described by Ingold and Hughes on the basis of kinetics and changes in optical rotation[1]. Recent work[2,3], however, has shown the need for caution in the practice which afterwards became fashionable of assigning these classifications on the basis of the optical result, unsupported by kinetic data, in other types of reaction, such as replacement of hydroxyl by halogen. The only unequivocal decision in such a reaction would seem to be the assignment of the exclusive S_N2 process to account for the isolation of, for example, optically pure (−)-2-chlorooctane from (+)-2-octanol. Isolation of the optically pure (+)-halide, retained configuration, does not necessarily point to the S_Ni, internal, mechanism, since this result could be due to a double S_N2 process, the first one being independent of halogen. Predominant inversion but with some loss in optical purity could be due to (S_N2 + S_N1 + S_Ni) or (S_N2 + S_N1) or (S_N2 + S_Ni), whereas predominant retention could be due to (S_N2 + S_Ni + S_N1) or (S_N1 + S_Ni) or (S_N2 + S_Ni), bearing in mind that the effect ascribed to S_Ni could be due entirely or partly to the double S_N2.

Alkyl rearrangement is usually taken as being indicative of a carbonium cation mechanism, although possibility of a bimolecular rearrangement process must be acknowledged.

(R = H or CH_3).

As a kinetic and optical result attributable to the S_N1 process need not lead to rearrangement in the alkyl group[2], absence of rearrangement does not necessarily exclude the S_N1 process, even with a group such as 2-octyl, which under various circumstances rearranges readily to 3- and 4-octyl.

Complications in interpretation can also arise because of loss of rotatory power and/or rearrangement after the initial formation of the halide, or from the lack of experi-

mental precision in analysing the halide product, that is, assessment of isomeric constitution.

The mechanism itself may change in the period during which the product is being formed, so that two or more mechanisms may contribute. In the alcohol–phosphorus trihalide systems, for example, the alkyl halide is produced by three consecutive reactions comprising the removal of the three alkyl groups of the trialkyl phosphite by hydrogen halide, the first two presumably being clean S_N2 processes, while the third involves rearrangement and loss in rotatory power for a secondary alkyl group[2]. The formation of isomerically pure *s*-alkyl halides by the first dealkylation led us to examine the related system in which an alcohol is treated with triphenyl phosphite and hydrogen or alkyl halide[4].

The main sequence of reactions appears to be as follows, although other sequences may contribute:

$$(PhO)_3P + ROH \rightarrow PhOH + (PhO)_2POR \xrightarrow[(R' = H, Me, etc.)]{R'X}$$

$$X^- \xrightarrow{S_N2} R\text{—}\overset{+}{O}PR'(OPh)_2 \rightarrow RX + R'PO(OPh)_2$$

In the original work[4] various optical results were obtained, for example, with $R'X$ = HCl, 2-octanol ($\alpha_D^{20\cdot4}$ − 7·83°, l = 1) gave 2-chloro-octane ($\alpha_D^{22\cdot2}$ + 18·8°, l = 1), thus showing a 40 per cent loss in optical purity, while with $R'X$ = $C_6H_5CH_2Cl$, an 18 per cent loss in activity was observed. These results indicate a mixture of mechanisms, with contributions from S_N2 and S_N1 modes according to conditions; although for certain reasons the original authors suggested the S_N2 mechanism.

We find, however, that at room temperature (or just above) this system ($R'X$ = HCl) gives 2-chloro-octane (α_D^{18} + 30·15° from ROH, α_D^{18} − 7·96°, l = 1) isolated by detailed fractionation of the primary product. This represents inversion without loss in rotatory power, and therefore presumably the clean S_N2 mechanism as originally suggested. It also points to the non-intervention of the possible ROH + HCl reaction[5], confirmed by the preparation of isomerically pure 2- and 3-chloropentanes in the triphenyl phosphite system. When $R'X$ = HBr or HI, some rearrangement occurred, namely, 3-bromopentane (25 per cent) and 3-iodopentane (10 per cent) from 2-pentanol. This effect could be due to the quicker interaction between the HBr or HI and the alcohol itself. *n*-Alcohols, however, still gave isomerically pure halides.

In the reaction of methyl bromide or methyl iodide with triphenyl phosphite and a secondary alcohol we appear to have an example in which the mechanism of formation of the halide changes with time, that is, as the reaction medium changes. From both 2- and 3-pentanol the highest yields (60–65 per cent) were obtained by heating the reactants at 100° C for 20 h (iodide, under reflux) or 42 h (bromide, in sealed tube), and all products contained about 5 per cent of the rearranged isomer. By restricting the yields to 40–50 per cent by a shorter period of heating (8 h) isomerically pure products were obtained. The possibility of isomerization after formation is discarded, because when the 2-halogenopentanes were heated in the presence of *n*-butanol, triphenyl phosphite, and methyl halide, as already mentioned, they were recovered unchanged. From the *n*-butanol isomerically pure halides resulted.

Resolution of Oxalato*bis*(ethylenediamine)-cobalt(III) Bromide by a Preferential Induced Crystallization

The resolution of oxalato*bis*(ethylenediamine)cobalt(III) bromide by way of the preferential crystallization of one optical enantiomorph was first demonstrated by Werner[1]. Seed crystals of optically active oxalato*bis*(ethylenediamine)cobalt(III) were added to a solution containing 2 g of the racemic compound. The subsequent addition of alcohol gave 0·2 g of dextro bromide in 95 per cent optical purity (sodium *D*-line rotations). A marked improvement of this resolution is reported here in which optically active *tris*(ethylenediamine cobalt(III) acetate is used.

Oxalato*bis*(ethylenediamine)cobalt(III) bromide (8·5 g) was shaken vigorously with silver acetate (about 4 g) suspended in hot water (73 ml., 70° C). The silver bromide was filtered off and to the filtrate was added a solution of D-*tris*(ethylenediamine)cobalt(III) acetate prepared as follows. D-*tris*(Ethylenediamine)cobalt(III) iodide (12·9 g)[2] was shaken vigorously with a suspension of silver acetate (about 10 g) in hot water (80 ml., 70° C). The silver iodide was filtered off and the filtrate evaporated to a volume of 18 ml. To the mixed acetate solutions a solution of potassium bromide (20 per cent w/v) was added. Table 1 shows the yields of optically active bromide obtained.

Table 1

Fraction	Potassium bromide added (ml.)	[Co ox(en)$_2$]Br (g)	$[\alpha]_D$*
1	5	1·3	−796
2	3	0·8	−796
3	5	1·6	+492
4	4	0·3	+236
5	5	1·0	+428

Fractions 1 and 2 were combined and recrystallized from hot water (10 ml.) containing potassium bromide (0·5 g) and gave 1·7 g of pure oxalato*bis*(ethylenediamine)-cobalt(III) bromide-1 hydrate (40 per cent of the theoretical yield). The analysis was as follows: calculated for $[Co(C_2O_4)(C_2H_8N_2)_2]Br.H_2O$; carbon, 19·73; hydrogen, 4·97; bromine, 21·9 per cent; found: carbon, 19·83; hydrogen, 4·99; bromine, 21·89 per cent. A 0·25 per cent aqueous solution in a 10-cm tube gave $[\alpha]_D$ −812.

Solutions of ammonium *d*-tartrate or ammonium *d*-camphor-10-sulphonate (10 per cent w/v) may be used instead of *tris*(ethylenediamine)cobalt(III) but lower yields of active oxalato*bis*(ethylenediamine)cobalt(III) were obtained (20 per cent compared to 40 per cent). In addition, the least-soluble fractions were now dextro-rotatory in the sodium *D*-line.

An attempt to resolve *cis*-dinitro*bis*(ethylenediamine)-cobalt(III) acetate by a method analogous to that described here using either optically active *tris*(ethylenediamine)cobalt(III) acetate or ammonium *d*-camphor-10-sulphonate gave only a 6 per cent yield of optically pure *cis*-dinitro*bis*(ethylenediamine)cobalt(III).

For the method to be generally applicable it is necessary that the optical forms of the complex be less soluble than the racemic form. The success of the resolution with oxalato*bis*(ethylenediamine)cobalt(III) is due no doubt to the large difference in solubilities of the active (1·05 g/100 ml. at 17° C) and inactive (1·85 g/100 ml. at 17° C) forms[1] together with the fact that the seed crystals are generated "homogeneously" throughout the solution, thus greatly improving the efficiency of the method.

Mason and Norman[3] recently reported circular dichroism produced in the region of the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition of the hexamminecobalt(III) cation by *d*-tartrate ion or *d*-camphor-sulphonic acid. The mode of the outer sphere interaction between these anions and the metal complex was tentatively suggested to involve chelate hydrogen bonding. The overall dipolar nature of the oxalato*bis*-(ethylenediamine)cobalt(III) cation would undoubtedly augment any hydrogen bonding in the interaction with the *tris*(ethylenediamine)cobalt(III) ion. However, other

* All rotations in this letter refer to the sodium *D* line.

factors must be involved since specific effects between the *tris*(ethylenediamine)cobalt(III) cation and the *tris*(2,2′-bipyridine)osmium(II) and (III) cations have been reported[4], where chelate hydrogen-bonding is not possible.

It appears probable that all these phenomena are but manifestations of configurational activity as originally proposed by Dwyer[5]. Therefore those optically inactive complexes for which activity effects have been observed should also display circular dichroism when in the presence of the optically active agent.

Relation between Thermodynamic Property Change and Vibrational Frequency Shift in Ethyl Halides

RELATIONS can be found by plotting the difference of the ideal gas state thermodynamic properties $\Delta S°$ and $\Delta C_p°$; formed between the thermodynamic property values of ethane, C_2H_6, and its homologues, C_2H_5X (X = F, Cl, Br, I), against the corresponding C–X bond stretching and C–C–X bond bending frequencies in ethyl halide series (Fig. 1). The results are presented in Table 1.

As the shifts in C–X bond stretching frequency with change in substituent in ethyl halide series correlate nearly linearly with the respective thermodynamic property increments in entropy, $\Delta S°$, and heat-capacity, $\Delta C_p°$, it seems plausible to believe that these stretching frequencies do not appreciably interact with other modes. The C–C–X bond bending frequencies although also yielding smooth curves (Fig. 1), however, have a greater degree of possible interaction.

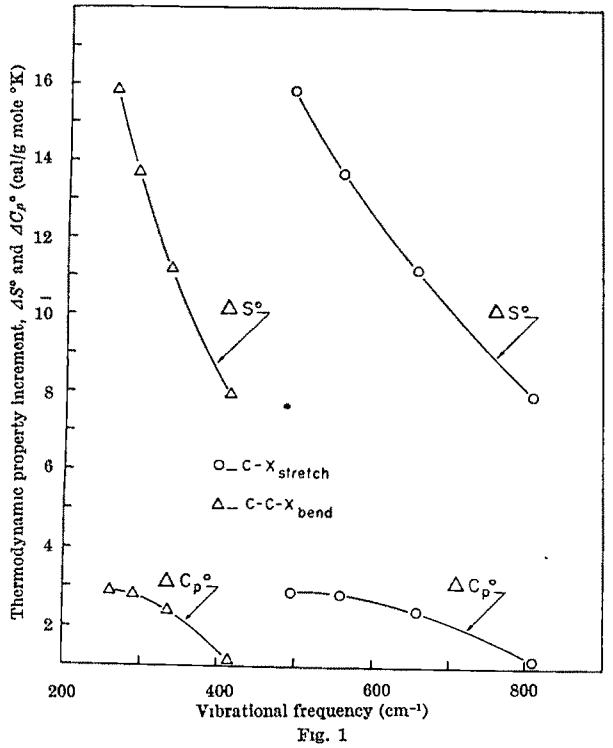

Fig. 1

Table 1

Compound	Thermodynamic property difference (at 298 16° K) (cal /g mole °K) $\Delta C_p°$	$\Delta S°$	Vibrational frequency (cm⁻¹) C–X stretch	C–C–X bend

BIOCHEMISTRY

Identification of the Yellow Lupin Growth Inhibitor as (+)-Abscisin II ((+)-Dormin)

THE presence of an abscission-accelerating substance in the pods of yellow lupin (*Lupinus luteus* var. Weiko II) was deduced by Van Steveninck[1]. He was able to show that the whorls of fertilized pods at the base of the inflorescence induced the abscission of younger, distal pods. Plants infected with pea mosaic virus underwent a different pattern of abscission suggesting that the hormonal balance was disturbed[2]. Paper chromatography of the acids extracted from lupin pods coupled with a wheat coleoptile extension assay revealed an inhibitory band which appeared to contain the factor controlling pod abscission[3].

A highly active and partly crystalline concentrate of the inhibitory material obtained from 700 kg of yellow lupin pods by Rothwell and Wain[4] has now been examined by a spectropolarimetric method recently described[5]. The sample showed a positive Cotton effect with extrema at 287 and 245 mμ and a profile identical with that of (+)-abscisin II. The ultra-violet absorption spectrum in alkaline and acidic ethanol was consistent with that of abscisin II (ref. 6) together with a superimposed, weak absorption peak at 237 mμ which could be attributed to an impurity. Based on absorbance at 262 mμ the molar amplitude of the Cotton effect was ~240,000°, which is in good agreement with that of (+)-abscisin II (ref. 5).

The inhibitory activity of the sample in the wheat embryo assay[6] was slightly less than twice that of synthetic racemic abscisin II used for comparison. Since we have previously shown[7] that (+)-abscisin II has about twice the inhibitory activity of the racemic compound, the spectropolarimetric assay is confirmed; the sample is largely (+)-abscisin II.

The identification of sycamore dormin as abscisin II extended the known range of this compound's physiological effects. Recently the dormancy inducing inhibitor in birch leaves[8] and the germination inhibitor in rosehips[9] have also been identified as (+)-abscisin II (ref. 5) so that the role of this compound in controlling dormancy is now well established. The identification of the lupin factor places its abscission-inducing role[10] on a firmer basis,

and shows also that abscisin II concentrations within the plant may be affected by a virus infection[2].

A Simple Bioassay for Gibberellic Acid*

IN his review of 1965, Paleg[1] outlined the many biological tests that have been used as quantitative assays for gibberellins. The lettuce hypocotyl test is perhaps the simplest to carry out, but the lowest concentration that can be reliably assayed is only 0·1 mg/l. The most sensitive assay is the barley endosperm test which detects concentrations as low as 0·0001 mg/l., but this method has the disadvantage that the procedure is both involved and laborious.

A method for detection of kinins has been reported by Osborne and McCalla[2] based on retardation of senescence in leaf disks of *Xanthium*. Fletcher and Osborne[3,4] more recently showed that senescence in leaf cells of *Taraxacum officinale* Weber is retarded by supplying gibberellic acid, GA_3 (GA). This effect was observed with concentrations as low as 0·001 mg/l. and has been made the basis of a simple bioassay for GA. This communication describes the method.

A continuous supply of *Taraxacum* leaves can be ensured by keeping potted plants in the greenhouse under natural light conditions. The oldest mature leaves from these plants or from those growing out of doors are suitable for use in this test. The leaves are detached, and if fully expanded and sufficiently mature they can be used immediately. If they are not sufficiently mature, the leaves are "aged" under a bell jar with their petioles in water until the glossy green colour fades to a uniformly pale green; this indicates that an appropriate stage of maturity has been reached.

Disks of a convenient diameter are punched from the interveinal portions of the leaf using a cork borer. Duplicate sets of disks are extracted at once with hot 80 per cent ethanol and the extracts stored in the dark for subsequent determination of the original chlorophyll contents. Other matched sets of disks are placed in Petri dishes on filter papers moistened with either water or one of a graduated series of GA concentrations. The abaxial surface of the leaf tissue is in contact with the moist filter paper. Care should be taken not to moisten the filter paper too much for this results in waterlogging and blackening of the disks. A satisfactory amount of liquid for a 7 cm diameter filter paper is 0·8 ml. The covers of the Petri dishes are lined with moist filter paper and the dishes are then placed in a plastic box to maintain high humidity, and stored in darkness at 25° C.

With properly "aged" starting material the disks in the water controls are uniformly chlorotic after 4 days, and the retention of chlorophyll in the treated disks is visibly greater with increasing concentrations of GA.

Each set of disks is then dropped into test-tubes containing hot 80 per cent ethanol and boiled gently. The test-tubes are then stoppered and transferred to an incubator at 37° C overnight to complete the extraction of chlorophyll. An alternative and quicker procedure is to boil the tubes gently in a water bath until all the chlorophyll has been extracted from the disks. The chlorophyll extracts are brought to volume with 80 per cent ethanol and the absorbancy of each solution and those of the initial controls are measured in a suitable colorimeter (in this instance, a Spectronic 20) at 665 mμ.

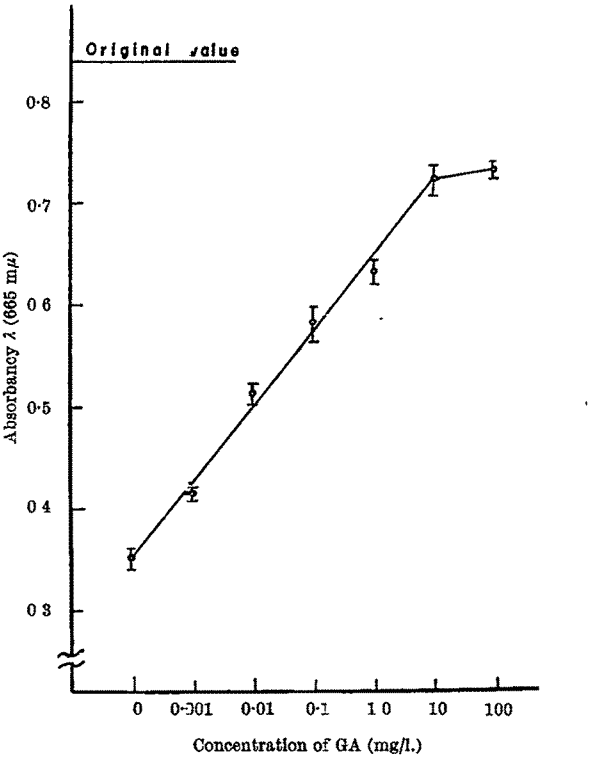

Fig. 1. Retardation of chlorophyll degradation in leaf disks of *Taraxacum officinale* by gibberellin (GA). Chlorophyll content expressed as absorbancy λ, 665 mμ of 80 per cent ethanol extracts at 0 and 4 days

When the absorbancies are plotted against concentrations of GA (Fig 1) there is a linear relationship from 0·001 to 10 mg/l. At higher concentrations this relationship is not maintained because a maximum value for chlorophyll retention is reached. Our earlier work[3] showed that at concentrations from 10 to 100 mg/l. the values lie on a plateau.

In order to determine the specificity of this bioassay, other growth substances, including indolyl-3-acetic acid (IAA), 6-furfurylaminopurine (kinetin), 2,4-dichlorophenoxyacetic acid (2,4-D) and α-naphthylacetic acid (NAA), were investigated. It was found (Table 1) that IAA and NAA did not retard senescence. Kinetin and 2,4-D produced effects somewhat similar to those produced by low levels of GA, but the concentrations required were several orders of magnitude greater than for GA.

This assay can be conveniently used for the quantitative determination of GA concentrations from 0·001 mg/l. to 10 mg/l. and for the qualitative detection of concentrations up to 100 mg/l. It does not require the use of elaborate

* This article was received in the office of *Nature* on June 20, 1966, five days before the appearance of an article by Whyte and Luckwill describing a similar method of assay applied to a different plant—Editor, *Nature*.

Table 1. CHLOROPHYLL CONTENT IN LEAF DISKS OF *Taraxacum officinale* TREATED WITH FIVE GROWTH SUBSTANCES

Sample	Treatment (mg/l.)	Absorbancy λ (665 mμ) GA	K	IAA	2,4-D	NAA
0 day	–	84	84	84	84	84
4 days	0	35	35	35	35	35
	0·001	42	37	34	37	37
	0·01	51	36	36	33	39
	0·1	58	35	34	37	31
	1·0	63	41	33	36	36
	10·0	72	50	33	42	39
	50 0	–	65	–	–	–
	100·0	73	–	36	49	37

Disks were maintained for 4 days on filter papers moistened with either gibberellin (GA); kinetin (K); indolyl-3-acetic acid (IAA); 2,4-dichlorophenoxyacetic acid (2,4-D); or α-naphthylacetic acid (NAA). Chlorophyll content expressed as absorbancy λ, 665 mμ in 80 per cent ethanol. The values are a mean of two experiments carried out in duplicate. The *S.E.* did not exceed ± 3·4.

equipment, complex media or sterile conditions. The greatest advantage lies in its simplicity and its specificity for low concentrations of GA.

This work was started at the Department of Agriculture, University of Oxford, and completed in the University of Guelph. We thank Prof. G. E. Blackman for his interest and encouragement. This investigation was supported by a grant from the National Research Council of Canada.

Biological Detection of Phytochrome in Callus Tissue of *Nicotiana tabacum* L.

DURING recent years, considerable information has been gained concerning the role of light in germination, etiolation, and control of flowering. The discovery of phytochrome has greatly aided the understanding of these processes. Briggs and Siegelman[1] found that seedling plants had highest phytochrome concentrations in regions of active cell division. We wished to know whether or not phytochrome had any function in actively dividing cells cultured from undifferentiated stem pith. This communication reports evidence that the phytochrome system was involved in growth of callus tissue cultured *in vitro* from undifferentiated pith from stems of *Nicotiana tabacum* L.

Sections of pith obtained from stems of normal plants of three varieties of *N. tabacum* were cultured and subcultured on a chemically defined nutrient medium. Callus tissue from all three of the varieties responded similarly and data are composited in the tables presented in this report. The basic medium (modified from Murashige and Skoog[2]) consisted of: sucrose, 20 g; ammonium nitrate, 1·65 g; potassium nitrate, 1·9 g; potassium dihydrogen phosphate, 0·17 g; $MgSO_4.7H_2O$, 0·37 g; $CaCl_2.2H_2O$, 0·44 g; $MnSO_4.H_2O$, 22·3 mg; $ZnSO_4.7H_2O$, 8·6 mg; *ortho* boric acid, 6·2 mg; $Na_2MoO_4.2H_2O$, 0·25 mg; potassium iodide, 0·83 mg; $CuSO_4.5H_2O$, 0·025 mg; $CoCl_2.7H_2O$, 0·025 mg; ethylenediamine tetraacetic acid, 22·4 mg; ferric sulphate, 10·67 mg; thiamine hydrochloride, 0·1 mg; nicotinic acid, 0·5 mg; pyridoxine hydrochloride, 0·5 mg; glycine, 2·0 mg; *myo*-inositol, 100 mg; *N*-acetyl-L-aspartic acid, 0·1 mg; kinetin, 0·2 mg; and agar, 6 g in 1 l. of distilled water. The *p*H of the solution was 6·0 before autoclaving at 15 lb. for 20 min. Successive subcultures were started at 2 or 4 week intervals with tissue pieces weighing about 40 mg. The tissues were cultured in standard 100 × 20-mm Petri dishes to enhance uniform illumination during treatments. Five uniform-sized pieces of tissue were distributed on the surface of 40 ml. of nutrient medium in each dish. Transparent tape was used to secure the covers, which were left on during entire experiments including time of illumination, to reduce airborne contamination.

Growth of tissues under light or in complete darkness was compared. The illuminated lots were subjected to 16-h periods of low intensity (20–30 ft.-candles) light from standard cool-white fluorescent lamps. All tissues were maintained at 26° ± 1° C. In a typical experiment (Table 1) the lighted lots were significantly heavier than those maintained in darkness. The higher average weight per piece of tissue was interpreted as an increased rate of growth in the lighted tissues.

Table 1. WEIGHTS OF *Nicotiana tabacum* CALLUS TISSUE CULTURED FOR 30 DAYS IN COMPLETE DARKNESS OR IN LIGHT AT 26° ± 1° C

Condition when weighed	Mean weight (mg) per tissue piece grown in: Darkness	Light
Wet*	711	883
Oven dried*	49	60

Mean wet weight per tissue piece at start of experiments was about 40 mg. Data are means of 60 pieces of tissue.
* Analysis of variance showed that differences between dark- and light-grown tissues were significant at $P = 0·01$. Variations between tissues within treatments were not significant.

Several experiments were carried out to determine whether the additional growth of the illuminated tissues was related to function of the phytochrome system. This was tested by moving tissues to darkness at 25° ± 0·5° C immediately after sub-culturing. Some tissues were kept continuously in darkness; others were given daily 5-min irradiations with red (2 μW/cm²/mμ at 660 mμ) or far-red (1·3 μW/cm²/mμ at 730 mμ) light to produce phytochrome in the far-red-absorbing (P_{fr}) or red-absorbing (P_r) form, respectively. As a test of photoreversibility, some tissues were given 5 min of red, to convert phytochrome to P_{fr}, followed immediately by 5 min of far-red, to revert it to P_r, each day from the previously described sources. After the brief exposures to red and/or far-red light, all the tissues were returned to darkness in the same 25° C incubator. All treatments were repeated daily for the duration of each experiment. Brief irradiation periods were used because prolonged exposure to far-red often causes the same response as that obtained from exposure to red light. This has been attributed to the weak overlapping of P_r absorption into the far-red region of the spectrum[3]. Duncan's multiple range test[4] was used to determine whether differences between treatments were statistically significant. Results of a typical experiment (Table 2) clearly show a promotion of growth in tissues irradiated with red light. The red-irradiated tissues were significantly heavier than the dark-controls and those that received far-red only. These data indicate that P_{fr} functioned in the growth of callus tissue sub-cultured from normal plants of *N. tabacum*. The fact that tissues irradiated with red, followed immediately by far-red, grew less than those irradiated with red alone shows a reversal of the effect of red light

Table 2. WEIGHTS OF *Nicotiana tabacum* CALLUS TISSUE CULTURED FOR 14 DAYS IN COMPLETE DARKNESS AT 25° C, OR WITH RED (*R*) AND/OR FAR-RED (*FR*) TREATMENTS

	Mean wet weight per tissue piece Dark	*FR*	*R*+*FR*	*R*
Mg/piece	223	229	249	282
M.R. test*	*a*	*a*	*ab*	*b*

Irradiations with *R* and *FR* were for 5 min at 24-h intervals for the duration of the experiment. Mean wet weight per tissue piece at start of experiment was about 40 mg.
* M.R. test, multiple range test. The difference between red-irradiated and dark-control was significant at $P = 0·01$. Means with a common letter did not differ at $P = 0·05$. Variation between tissues within treatments were not significant.

and is further evidence that the phytochrome system was involved.

Enzymatic Degradation of L-Cystine by Cytoplasmic Particles from Cabbage Leaves

THE degradation of cystine by cystathionase preparations from liver[1] and *Neurospora*[2] has been reported. A highly purified cystathionase from *Neurospora* catalysed the cleavage of cystine to pyruvate, ammonia and thiocysteine[3]. L-Cystine was utilized at only 17 per cent of the rate of cystathionine. A second cystathionine cleavage enzyme which utilizes L-cystine at the same rate as cystathionine has recently been found in *Neurospora*[3]. We have found that homogenates of cabbage leaves can be fractionated into particulate and soluble cytoplasmic fractions, both possessing a heat-sensitive ability to degrade L-cystine to pyruvate. The two enzymatic activities appear to have different characteristics. The present communication briefly reports on some of the properties of the particulate enzyme.

Cabbage leaves were homogenized in a solution of 0·25 M sucrose which was 0·01 M with respect to sodium phosphate at *p*H 7·2. One ml. of homogenizing medium was used for each g of tissue. All operations were carried out at 4° C. The homogenate was passed through cheesecloth and then centrifuged at 1,000*g* for 10 min. The precipitate was discarded, and the homogenate then centrifuged for 1 h at 70,000*g*. The supernatant solution, which contained the soluble enzyme, was decanted. The sedimented particles were washed by being resuspended in the sucrose–phosphate buffer and recentrifuged. The particles were then suspended again in fresh sucrose–phosphate solution and dialysed overnight against the same medium. The final suspension contained the particles from 10 g of leaves per ml. of suspension. The protein concentration varied from 30 to 60 mg per ml.

It was found that the *p*H optimum of the reaction was a broad peak between *p*H 8·5 and 8·9. The customary reaction mixture consisted of the following in a final volume of 1 ml.: 200 μmoles *tris* buffer, *p*H 8·7, 10 μmoles L-cystine, and 0·1 ml. of the dialysed, washed particle suspension. The reaction was stopped by the addition of 2 ml. of 10 per cent trichloroacetic acid, and the denatured protein removed by centrifugation. The formation of pyruvate was followed by colorimetric assay of its 2,4-dinitrophenylhydrazone[4].

The evidence that the particulate and soluble enzymes are different consists of the following: (*a*) continued washing and re-sedimentation of the particles does not release further soluble enzyme; (*b*) the activity of the particulate enzyme is stimulated from 40 to 100 per cent by the addition of 5×10^{-5} M pyridoxal-5′-phosphate, whereas the soluble enzyme shows essentially no stimulation; (*c*) sonic oscillation of the particles yielded a soluble fraction which retained the property of having a large stimulation of activity on the addition of pyridoxal-5′-phosphate. Pyridoxal could not replace pyridoxal phosphate. The substrate specificity of the particulate enzyme is shown in Table 1.

There appears to be a small activity with D-cystine and L-cysteine. Both may be reflexions of a small contamination of L-cystine in the substrate. Significantly, L-cystathionine is completely inert as a substrate. This distinguishes this enzyme completely from the liver and *Neurospora* cystathionases. Also of interest is the fact that L-cysteine-S-SO_3, which has been suggested as an intermediate in sulphate reduction in moulds[5], is an even better substrate than L-cystine. This may be of some physiological significance.

The inhibition of the reaction by carbonyl reagents is shown in Table 2. Pyridoxal phosphate-requiring enzymes are very strongly inhibited by such reagents. The inhibition by hydroxylamine is very large even at a concentration as low as 1×10^{-5} M. We have found that L-cysteine is an excellent inhibitor of the reaction with L-cystine. At equimolar concentration it inhibits the reaction almost completely, and at 2×10^{-5} M it inhibits it by 70 per cent. D,L-Homocysteine is also very effective as an inhibitor, but D,L-homocystine is almost inactive. Reduced glutathione is intermediate in action, inhibiting 42 per cent at equimolar concentration with the L-cystine. Ethylenediamine tetraacetate gave only a 15 per cent inhibition at a concentration of 10^{-3} M.

The proof that pyruvate is a product was obtained by use of an isotope dilution procedure. A reaction mixture containing 0·3 μmoles of D,L-cystine-1-^{14}C which had 2 μc. of activity, 0·05 μmoles of pyridoxal phosphate, 200 μmoles *tris* buffer of *p*H 8·7 and dialysed washed particles was incubated for 2 h and then stopped and the particles removed as usual. Two mmoles (220 mg) of sodium pyruvate were added to the reaction mixture and followed by excess 2,4-dinitrophenylhydrazine. The precipitate was collected, dissolved in a chloroform–ethanol (20 : 80) solution and the hydrazones extracted into 1 N sodium carbonate. The sodium carbonate solution was acidified and the hydrazones extracted back into the chloroform–ethanol solution. The latter was brought to dryness *in vacuo*, and then the residue recrystallized three times, first from water, followed by ethyl acetate, and 70 per cent ethanol. Weighed samples were dissolved on planchets and dried and then counted in a gas flow counter. Table 3 summarizes the results. There appears to be little doubt that pyruvate is formed during the reaction. Tests for ammonia formation were positive, but no sulphydryl groups could be detected. The rate of formation of pyruvate was not constant, and the reaction

Table 1. SUBSTRATE SPECIFICITY OF THE PARTICULATE ENZYME

Substrate	Final concentration (M)	Relative activity
L-cystine	1×10^{-3}	100
L-cystathionine	1×10^{-3}	0
D-cystine	1×10^{-3}	11
L-cysteine	2×10^{-3}	10
S-methyl-L-cysteine	2×10^{-3}	0
D,L-homocysteine	2×10^{-3}	0
D,L-homocystine	1×10^{-3}	10
L-cysteine-S-SO_3	1×10^{-3}	152

Reaction system was as described in the text except the substrate was as shown above. Incubation time was 60 min.

Table 2. INHIBITION BY SODIUM CYANIDE AND HYDROXYLAMINE

Inhibitor	Final concentration (M)	Relative activity
None	—	100
Sodium cyanide	1×10^{-3}	8
	1×10^{-4}	70
Hydroxylamine	1×10^{-3}	0
	1×10^{-4}	0·5
	1×10^{-5}	5

Reaction mixture was as described in the text but including the inhibitor as shown.

Table 3. SPECIFIC ACTIVITY OF THE RECRYSTALLIZED PYRUVIC ACID 2,4-DINITROPHENYLHYDRAZONE

Sample	Specific activity (c.p.m./mg)
Chloroform–ethanol residue	393
First recrystallization from water	399
Second recrystallization from ethyl acetate	385
Third recrystallization from 70 per cent ethanol	380

stopped when 15–20 per cent of the cystine had disappeared. Whether this is due to product inhibition has not been ascertained, since all the products, particularly the sulphur-containing ones, have not been identified.

We are at present purifying the soluble enzyme and investigating its properties in detail. These results will be reported elsewhere. The present work was supported by a grant from the National Institutes of Health, U.S. Public Health Service.

Purification of Insulin labelled with Iodine-131

THE procedure described by Hunter and Greenwood[1] with some minor modifications has been used in this laboratory for small-scale preparation of iodine-131-labelled insulin. About 1·2 mc. iodine-131 from Kjeller is used in a volume of less than 0·025 ml. for the labelling of 5 μg of purified insulin. The iodination efficiency is usually in the region of 60–80 per cent, giving a specific activity of about 150 μc. iodine-131 per μg insulin.

Various purification techniques for iodine-131-labelled insulin have been reported[2–4]. In some experiments we used the method devised by Banerjee and Gibson and found it possible to purify the reaction mixture in one operation only, thus omitting the dialysing step for removal of free iodine-131.

0·2 ml. of human serum albumin solution (20 mg albumin per ml. buffer) was added to the reaction mixture prepared according to Hunter *et al.* A column of 1 g 'Sephadex *G*–50' gel (fine) was prepared, and 0·07 M sodium barbitone buffer (*p*H 8·6) was used as the elution medium. The column was about 600 mm long and had an inner diameter of 6 mm. After slow elution, the various fractions were examined for radioactivity and analysed by paper chromatography and paper electrophoresis.

The elution pattern obtained from three experiments was as follows: (1) Altered or damaged insulin which came out together with the serum protein and some unaltered insulin in the first 6 ml. eluate showed 5–25 per cent of the total activity. (2) Purified insulin which held 35–57 per cent of the total activity and 2–4 per cent impurities was contained in the next 2 ml. portion. The impurity is assumed to be insulin which has been altered when the material passes through the column. This fraction was collected and diluted in 0·5 per cent serum albumin solution immediately after elution and then subjected to deep freezing. The last portion (8–25 ml.) mainly contained free iodine-131. Usually less than 10 per cent of the total activity is absorbed to the column.

Determination of pure and altered insulin was performed using ascending paper chromatography and two different solvents (barbital buffer, *p*H 8·6 (ref. 4), and a mixture of *n*-butanol, acetic acid and water[5]). Free iodine-131 was determined by paper electrophoresis in which 0·1 N sodium hydroxide was used as electrolyte[6].

Isolation of the Scent-trail Pheromone of an Australian Termite

THE trail-laying capabilities of termites have been known for many years and, quite recently, this activity has been shown[1,2] to be based on pheromones produced by the sternal gland. Both primitive and advanced termites possess such a gland, which consists of a rather diffuse structure beneath the fifth abdominal sternite[3]. In two species, namely *Zootermopsis nevadensis* (Hagen) (Hodotermitidae)[1,2] and *Nasutitermes corniger* (Mots.) (Termitidae)[3], extracts of the appropriate region, or indeed of the whole insects, could be used to lay artificial trails that were readily followed by the parent termites. However, no clear indication of the chemical nature of the pheromones involved has yet been published.

In the present work, a scent-trail pheromone common to several Australian species of *Nasutitermes* has been isolated and characterized as an unsaturated diterpenoid hydrocarbon, $C_{20}H_{32}$. The mainstay of the investigation has been the southern, ground-nesting termite *Nasutitermes exitiosus* (Hill). This species has the advantage that it is available in large quantities and it shows a comparatively "docile" disposition in culture which is admirably suited to the requirements of a reliable biological test. In the absence of repellent substances, both soldiers and workers readily follow artificial trails traced on paper from ethereal pheromone, over the range of concentrations about 10^{-3}–10^{-5} g/ml., although above and below these limits there is little or no response. Thus, to test a preparation for trail-laying activity, it is necessary to use several successive tenfold dilutions in order to cover the possibility that pheromone may originally be present at too high a concentration.

In such a test, the *exitiosus* pheromone was shown to be extractable from homogenized termites by light petroleum, and to be stable to alkaline hydrolysis. The unsaponifiable fraction of the extract in light petroleum was refined by means of chromatography on a dry column of alumina (activity I). Under these conditions, inactive saturated hydrocarbons were the first to emerge, followed by colourless unsaturated hydrocarbons and later by bright orange–yellow β-carotene (identified by its characteristic absorption between 300 and 550 mμ). Trail-laying activity was confined to the colourless unsaturated fractions, and vacuum distillation of these, to which a little *n*-eicosane had been added as a carrier, afforded an active, volatile fraction, b.p. 120°–220° (bath temperature), at 25 min of mercury.

The active fraction was next subjected to thin-layer chromatography on silica gel, with light petroleum as the mobile phase. Treatment of a longitudinal section of the chromatogram with cold concentrated sulphuric acid revealed five major bands as purplish spots, fading to pale brown, with approximate R_F values of 0·0, 0·15, 0·4, 0·6 and 0·85. Saturated materials travelled with the solvent front. Trail-laying activity was associated with the R_F 0·4 zone, and elution of this separated portion of the chromatogram with light petroleum gave a few milligrams of a highly-active, colourless oil. Gas chromatography at 175° (on a Pye 'Argon' instrument, with a 120-cm by 4-mm column, packed with 10 per cent silicone oil on 'Celite', and a gas flow of 75 ml./min) showed that this material was made up of two components with retention times of 2·7 and 14·5 min respectively, and suggested molecular complexities of C_{15} and C_{20}. Resolution of the binary mixture was achieved either by preparative gas chromatography at 225° (120-cm by 1-cm column, packed with 10 per cent 'Apiezon-*L*' on 'Celite', and a gas flow of 100 ml./min), or by short-path, fractional distillation at 25 mm. Progress in either case was monitored on the analytical gas chromatograph. The former method gave products of high purity, but recoveries were low and the latter was preferred for most purposes. Only the higher boiling substance was active in the trail-laying test and

the amounts isolated from active insects indicated a natural content of about one part in four million. However, with hibernating termites, the pheromone titre fell considerably.

The molecular weight of the pheromone was determined by mass spectrometry as 272, thereby confirming a diterpenoid hydrocarbon constitution. The ultra-violet spectrum (in *cyclo*hexane) showed only end absorption above 220 mμ and the infra-red spectrum (liquid film) included strong bands at 3,070, 1,640 and 880 cm^{-1}, which suggested one or more α-substituted vinyl groups. On catalytic hydrogenation, the pheromone gave an inactive octahydro-derivative (molecular weight 280, by mass spectrometry) and it presumably has a monocyclic structure, with four isolated double bonds.

An apparently identical pheromone has been isolated in small amounts from the arboreal termites, *Nasutitermes walkeri* (Hill) and *N. graveolus* (Hill), using *N. exitiosus* as the test animal. However, the pure pheromone shows no activity with the more distantly related *Coptotermes lacteus* (Froggatt) and it may therefore prove to be genus specific. Screening tests (with *exitiosus*) of various essential oils have also revealed activity in one plant species, namely the West Australian sandalwood, *Eucarya spicata* (R. Br.) Sprag. and Summ. Preliminary isolation experiments with this material indicate that activity is definitely associated with the small diterpenoid hydrocarbon fraction of the oil, and probably with a specific component which parallels closely, in thin-layer and gas chromatography, the behaviour of the true pheromone. Attempts are now being made to obtain this plant constituent in a state of purity.

Final confirmation of the nature of the pheromone must await an unambiguous synthesis. However, the possibility, always present in this type of work, that the substance isolated merely represents a carrier for an even more potent pheromone seems in the present instance rather remote.

I thank Dr. J. S. Shannon for the mass spectrum of the pheromone and Dr. J. D. Morrison for the mass spectrum of its perhydro-derivative.

A Biochemical Factor in the Zonation of Marine Molluscs

THE trochids *Monodonta turbinata* and *Gibbula divaricata* are midlittoral and sublittoral animals respectively. On the rocky shores of Malta, *M. turbinata* is found semi-exposed in the very narrow "intertidal" zone. *G. divaricata* is usually found submerged in shallow water. It was considered that *G. divaricata* might be adapted for prolonged submersion by having among other factors a higher capacity to incur an oxygen debt than *M. turbinata*. The experiments described here were carried out to test this hypothesis.

The snails were removed from the shells, weighed and finely minced with scissors. The operculum was discarded. The minced tissue was homogenized with sea water containing 10 mM sodium fluoride. The homogenate contained 10 per cent snail tissue. 1 ml. homogenate was incubated for 30 min at 25° C with 0·8 μmoles pyruvate and 1·3 μmoles nicotinamide-adenine dinucleotide (NADH) in a final volume of 2 ml. In one set of experiments the amount of pyruvate consumed by the reaction mixture was determined. The pyruvate was estimated as the dinitrophenylhydrazone. The oxygen consumption of the reaction mixture was measured with a Warburg respirometer in another set of experiments. The gas phase was air. The results were expressed in μmoles pyruvate or oxygen consumed per minute per gram dry weight of homogenate. The dry weight determinations were made on the material precipitated from the homogenate by trichloroacetic acid; this material was washed twice with distilled water and dried at 110° C for 24 h.

The mean rates of pyruvate and oxygen consumption observed are given in Table 1.

Table 1

	Pyruvate consumption (μmoles/min/g dry wt.) (Mean ± S.E.)
M. turbinata	1·54 ± 0·08 ($n = 5$)
G. divaricata	1·94 ± 0·06 ($n = 5$)
	Oxygen consumption (μmoles/min/g dry wt.) (Mean ± S.E.)
M. turbinata	3·04 ± 0·10 ($n = 3$)
G. divaricata	2·26 ± 0·04 ($n = 3$)

The difference between the mean rates of pyruvate consumption is significant ($0·002 < P < 0·01$). The mean rates of oxygen consumption also differ significantly ($P = 0·002$). Because 1 mole of pyruvate requires 2·5 moles of oxygen for its complete oxidation, it will be seen that the pyruvate consumed by the homogenates was not completely oxidized. The pyruvate which was consumed but not oxidized may be regarded as an oxygen debt as NADH was added to the reaction mixtures to favour the reduction of pyruvate to lactate. The homogenized tissues of *G. divaricata* consumed pyruvate at a higher rate and oxygen at a lower rate, and showed a greater oxygen debt as defined here, than the homogenized tissues of *M. turbinata*. This property may enable *G. divaricata* to withstand longer periods of submersion than *M. turbinata*.

Paralytic Shellfish Poison: Serological Assay by Passive Haemagglutination and Bentonite Flocculations

PARALYTIC shellfish poison (PSP) is a potent toxin, of small molecular weight ($C_{10}H_{17}N_7O_4.2HCl$), which is produced by the dinoflagellate *Gonyaulax catenella* and which is concentrated, with no ill effects, in bivalves that use the *Gonyaulax* as a food source[1]. Human ingestion of PSP results in paralytic poisoning and occasionally death[2]. Mouse bioassay is nowadays used for the detection of PSP in contaminated bivalves. This test, however, is not specific, as other marine toxins, such as puffer fish poison (tetradotoxin), produce similar paralytic symptoms in mice[3]. Recently, PSP was shown to be haptenic when conjugated to proteins by formaldehyde condensation[4].

This report compares passive haemagglutination and bentonite flocculation with mouse bioassay for the specific detection of PSP in contaminated shellfish. The approach used here for the sensitive and specific detection of PSP in bivalves should be applicable to the serological study of other marine toxins.

Details of the source of purified PSP, preparation of PSP-protein conjugates, production of antisera to PSP in rabbits, passive haemagglutination (HA), and haemagglutination-inhibition (HI) have previously been described[4]. Non-toxic butter clams (*Saxidomus giganteus*)

Table 1. INHIBITION AND RECOVERY STUDIES WITH PSP THAT HAD BEEN ADDED TO NON-TOXIC CLAMS USING PASSIVE HAEMAGGLUTINATION, BENTONITE FLOCCULATION, AND MOUSE BIOASSAY

PSP added per 100 g of clams (μg)	PSP recovered per 100 g of clams as measured by mouse bioassay (μg)	Minimal amount of PSP per ml. completely inhibiting a 4+ haemagglutinating dose of anti-PSP (μg)		Minimal amount of PSP per ml. completely inhibiting a 2+ bentonite flocculating dose of anti-PSP (μg)	
		Based on amount added to clams	Based on amount recovered by mouse bioassay	Based on amount added to clams	Based on amount recovered by mouse bioassay
200	50 2	0 032	0·008	0 25	0 063
600	331 2	0·048	0·026	0 375	0 2
1,000	621	0 04	0·025	0 31	0 19
1,400	1,045·8	0 052	0·039	0 22	0 16

were obtained from A. K. Sparks, University of Washington, Seattle. Varying amounts of a solution of purified PSP (5,000 μg per ml.) in acidified distilled water (*p*H 3·2) were added to constant amounts of the ground clams. The concentration of PSP in the clams was expressed in μg PSP per 100 g of clams. Saline extracts were made of the clams[5], and portions of these were quantitatively assayed for PSP by the mouse bioassay technique[6], while other portions were heated at 56° C for 30 min. The precipitate formed by heating was removed by centrifugation, and the supernate was used in HI and bentonite flocculation inhibitions. Bentonite flocculations (BF) were performed as previously described[7], using 1 per cent bovine serum albumin as the stabilizing agent. Bentonite flocculation inhibition (BFI) was carried out by serial dilution of the inhibitor in 0·1 ml. volumes in physiological saline in 10 by 75 mm tubes. To each dilution of inhibitor was added 0·1 ml. of anti-PSP serum in phosphate-buffered saline, *p*H 7·2. The serum had been diluted to contain a 2+ agglutinating dose of anti-PSP in 0·1 ml. after it was mixed with the inhibitor. After incubating at room temperature for 20 min, 0·1 ml. of each dilution of the mixture of inhibitor and anti-PSP was added to microflocculation slides, and bentonite flocculations were carried out.

Passive haemagglutination titres of PSP antisera varied from 1 : 16 to 1 : 1,024, 2 to 32 times greater than the BF titres. The antigen for HA, however, had to be prepared daily, whereas the bentonite antigen was stable for 4 days when stored at 4° C.

Data on HI and BFI with PSP that had been added to non-toxic clams are presented in Table 1. Minimal concentrations of PSP that completely inhibited anti-PSP are given on the basis of both the amount of PSP added to 100 g of clams and the amount of PSP recovered from 100 g of clams, as indicated by mouse bioassay. The term "recovered" is used here to indicate the amount of PSP detected by bioassay when known amounts had been added to non-toxic clams. Regardless of the amount of poison added to the clams (200, 600, 1,000 and 1,400 μg), the minimal concentrations that consistently inhibited anti-PSP were relatively similar for the individual tests—0·032, 0·048, 0·04 and 0·052 μg PSP per ml. for HI; and 0·25, 0·375, 0·31 and 0·22 μg PSP per ml. for BFI. The percentage of recovery of PSP by mouse bioassay increased with an increase in the amount of PSP added to the clams. The percentages of recovery for the 200, 600, 1,000 and 1,400 μg PSP clams were, respectively, 25·1, 55·2, 62·1 and 74·7 per cent. On the basis of the amount of PSP recovered by mouse bioassay, the clams that received 200 μg PSP, therefore, appeared to be most sensitive in inhibiting anti-PSP in both HA and BF (0·008 μg PSP per ml. for HI and 0·063 μg PSP per ml. for BFI). Obviously, the PSP that remained undetected by mouse bioassay was still active serologically. The specificity of the reaction is indicated by the fact that non-toxic butter clams (*Saxidomus giganteus*) and puffer fish poison did not inhibit anti-PSP in either test. HI was the more sensitive of the two serologic tests for the detection of PSP, but BFI involved the more stable antigen. Mouse bioassay detects a minimum of 0·18 μg PSP per ml. It follows that HI is considerably more sensitive in the detection of PSP than bioassay, while BFI is similar in sensitivity to the mouse test.

The data presented here indicate that HI and BFI are applicable to the serological detection of PSP in contaminated bivalves.

Use of Liquid Ion Exchange Chromatography for the Separation of Organic Compounds

SEVERAL investigators have recently effectively separated metals by means of paper or thin-layer chromatographic systems using liquid ion exchangers[1–6]. With these materials, this technique can be considered as a form of reverse phase chromatography whereby the liquid stationary phase is an acid or a base with very low solubility in the aqueous mobile phase. It seems that the interaction between ionized groups of the solutes and the stationary phase may play a significant part in this separation process.

Although solvent extraction with liquid ion exchangers was used successfully in the separation of organic compounds[7], the potentialities of liquid ion exchange chromatography have yet to be explored in this field.

During the course of development of a liquid chromatographic system which provided both close control of operating parameters and a degree of versatility characteristic of gas chromatography, it was found that liquid ion exchangers proved to be useful stationary phases for the separation of certain non-volatile organic materials.

A block diagram of the instrument used in this investigation is depicted in Fig. 1. The system consists of the micro packed column, those parts necessary for maintaining a controlled continuous flow of the liquid mobile phase, a temperature controller, a sampling device, a detector and recorder. For the continuous detection of nucleic acid constituents as well as other ultra-violet absorbing solutes a Perkin–Elmer Hitachi '*UVIS*-139' spectrophotometer was modified to accommodate a micro flow cell having an effective cylindrical bore 5 mm long and 1 mm in diameter. The cell was kept under pressure by restricting the flow at the outlet in order to avoid the generation of bubbles during operation. The detector signal was monitored with a 1-mV recorder provided with a base line compensator. Full-scale deviation of the recorder pen corresponded to 0·045 absorbance unit.

The sample was introduced by a high pressure sampling valve equipped with a slide for 10-μl. sample. The valve

was filled with the same solution by means of a hypodermic syringe before the sample was introduced into the apparatus. All parts of the instrument which had contact with the mobile phase were made of stainless steel, nylon or 'Teflon'. The detector cell was made of quartz. Special care was taken to minimize dead volumes between the sampling valve and the detector outlet. 'Swagelok' fittings were used for all connexions.

Columns were made of siliconized nylon tubing (1·6 mm outer diameter and 0·85 mm internal diameter), dry packed with the column material and plugged with porous 'Teflon' disks at both ends. A device ('precolumn'), prepared in a similar manner to the separation column, was placed upstream to the sampling valve for conditioning the mobile phase.

The chromatograms in Figs. 2 and 3 show separations of thyroid compounds and nucleic acid constituents. These were obtained by means of liquid ion exchange columns. The stationary phase was 'Aliquat 336' (General Mills Co.), a mixture of quaternary salts of long-chain tertiary amines, and mainly tricaprylyl methyl ammonium chloride in 75 per cent aqueous isopropanol solution. 'Chromosorb *P*' mesh fractions 230–270 and 270–325 (Johns-Manville Co.) were used as the solid support.

The support was soaked with a solution of 'Aliquat 336' in diethylether and the solvent was evaporated. The coated support was then boiled with the mobile phase for 10 min and after cooling the liquid was decanted. The column material was dried in air for several hours and then placed in the nylon tube by the usual vibration technique.

Before commencing the analysis, the columns were conditioned overnight in a stream of the mobile phase at 50° C and 15 atm. inlet pressure. During this time the columns became deaerated and some entrainment of the liquid stationary phase and compression of the packing occurred. A few centimetres of the inlet end of the columns was then removed and a stable base line obtained. The columns were used continuously over a period of several days and did not show any alteration in their resolving power. The operating conditions of the column are described in the captions. On several occasions a programmed increase of the flow rate during a chromatographic run, as shown for example in Fig. 3, resulted in a decrease in analysis time.

Other liquid ion exchangers, such as 'Amberlite *LA*-1', 'Amberlite *LA*-2' (Rohm and Haas Co.) and di-2-ethylhexyl-phosphoric acid also were used on 'Chromosorb *P*' support for preparing stable columns with suitable flow characteristics. Preliminary results indicate that they too efficiently separate organic compounds of distinct acidic or basic character.

Fig. 1. PHARMACOLOGY

Cholinergic Mechanism of Depressor Response to Small Doses of Adrenaline

MOORE and Puriton[1] in an early report in the literature state that small doses of ox adrenal extract reduce the blood pressure of the dog, but large doses increase it. The same observations have been reported by Cannon and Lyman[2] and by Dale and Richards[3]. This depressor response is not to be confused with that noted after the injection of larger doses of adrenaline or splanchnic nerve stimulation in the presence of α-adrenergic blocking agents such as dibenamine[4]. The latter observation is now explained on the basis of the unopposed stimulation of β-adrenergic receptors based on the receptor classification of Ahlquist[5].

Experiments in our laboratory have demonstrated a depressor response associated with the injection of small doses of adrenaline which appears to be cholinergic[6]. Under special circumstances, this can also be shown with noradrenaline and isoproterenol. Experiments have been carried out to elucidate the mechanism of this depressor response.

All experiments were carried out on anaesthetized dogs and cats without regard for sex or weight. The dogs were anaesthetized by intravenous injection of pentobarbitol sodium, 35 mg/kg, and the cats were anaesthetized by the intraperitoneal administration of chloralose dissolved in polyethylene glycol 200 at a dose of 80 mg/kg. All drugs were injected through a cannula placed in the femoral vein. The blood pressure was recorded from a carotid artery cannula by using a 'Sanborn' differential transformer-transducer coupled to an Offner 'Dynograph'. All drug doses were expressed in terms of the following salts: *l*-adrenaline bitartrate, *dl*-noradrenaline bitartrate, *l*-isoproterenol sulphate, phenoxybenzamine hydrochloride, dichloroisoproterenol hydrochloride (DCI), acetylcholine bromide and atropine sulphate.

Adrenaline administered to an animal at a dose of 1 μg/kg elicits a depressor response of approximately 20–35 mm of mercury as shown in Fig. 1. Repeated administrations of this dose at intervals yield smaller depressor responses and finally a pressor response or no response at all. This state of tachyphylaxis can be abolished by the administration of 10 μg/kg of acetylcholine, following which 1 μg doses of adrenaline again produce the depressor responses in the blood pressure.

Fig. 2 shows the interaction of various sympathomimetic amines with acetylcholine. The uppermost tracing shows a pressor response to a dose of adrenaline. After acetylcholine administration, adrenaline produces a depressor response on the first trial and somewhat less response on the second trial. Another dose of acetylcholine is administered which ordinarily would have re-established the depressor response to adrenaline. The administration of atropine, however, blocks the depressor response and a pressor response is obtained. The middle tracing shows the response to noradrenaline of an animal which had been treated with the α-blocking agent, phenoxybenzamine. The same sequence of events is shown as in the experiment with adrenaline. The bottom tracing shows the use of isoproterenol in the presence of the β-blocking agent DCI.

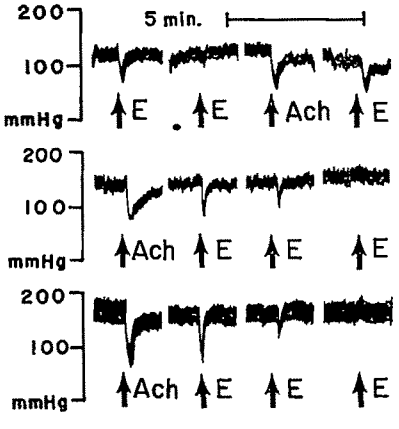

Fig. 1. Selected segments taken from a continuous record of the carotid blood pressure of an anaesthetized dog. E is *l*-adrenaline bitartrate (1 μg/kg) and Ach is acetylcholine bromide (10 μg/kg)

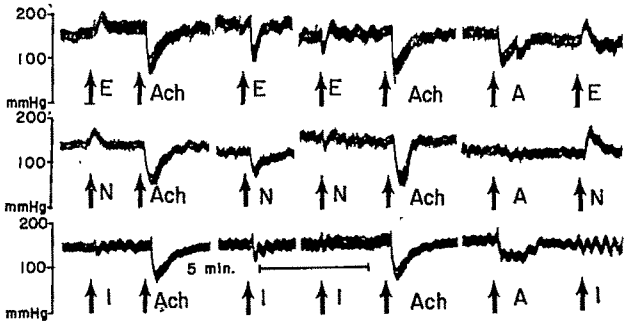

Fig. 2. Selected segments of records of the carotid blood pressure of three anaesthetized cats. E is *l*-adrenaline bitartrate (1 μg/kg), N is *dl*-noradrenaline bitartrate (1 μg/kg), I is *l*-isoproterenol sulphate (0 1 μg/kg), Ach is acetylcholine bromide (10 μg/kg) and A is atropine sulphate (1 mg/kg). See text

The tachyphylaxis to the small doses of adrenaline suggested that this phenomenon might be associated with a release of some agent which caused the depressor response. The elimination of the tachyphylaxis by injection of acetylcholine is taken as evidence that acetylcholine is liberated by a very small dose of adrenaline and that a dose of 10 μg/kg is sufficient to replete the stores. The blockade of the depressor response under consideration by a dose of atropine is taken as evidence that the depressor response is due to a muscarinic action. The production of depressor responses by noradrenaline in the presence of phenoxybenzamine and isoproterenol in the presence of DCI rules out the participation of α- and β-adrenergic receptors in this observation.

Many examples of the release of adrenergic mediators by cholinergic mechanisms exist at the present time[7]. The literature yields relatively few references to the release of acetylcholine by adrenaline[8,9].

Krayer and Verney[10] reported an increase in the acetylcholine content of the coronary sinus elicited by the administration of adrenaline. This was due to a reflex stimulation of the vagus and was eliminated by vagal section. Boatman[11] has observed a vasodilation in the hind limb of the newborn dog which is elicited by nerve stimulation and eliminated by atropine. When animals reach an age of 2 weeks, nerve stimulation produces only vasoconstriction. A recent publication by Kulkarni *et al.*[12] has shown that adrenaline produces depressor responses in animals infused with acetylcholine.

It is not possible to demonstrate the interaction between acetylcholine and the sympathomimetic amines in all animals. The effect was best demonstrated in animals during autumn and the susceptibility decreased during the winter months. In late winter only one animal in twenty-two was found to give the desired response. This may be the reason why such observations have not been reported previously. No correlation with age or sex of the animal could be made in our laboratory.

The site at which the acetylcholine is released by adrenaline to yield a depressor response has not been determined. Until it has been determined which vascular bed is being affected, the physiological significance is uncertain. In view of the small doses involved, the

release of acetylcholine by adrenaline could occur under physiological conditions.

We thank Miss Shannon Klug for technical assistance.

Modification of the Auditory Flutter Fusion Threshold by Centrally Acting Drugs in Man

PERCEPTUAL fusion of intermittent random noise stimuli at critical frequencies in man was first reported by Miller[1] and Miller and Taylor[2], and confirmed by Symmes, Chapman and Halstead[3]. The process is analogous to visual flicker fusion. The critical interruption rate at which fusion occurs is termed the "auditory flutter fusion threshold".

In view of the sensitivity of visual flicker fusion thresholds to the actions of psychotropic drugs, it is perhaps surprising that the psychopharmacology of auditory flutter fusion threshold has received little attention. Only Eysenck and Easterbrook[4] appear to have explored this field and they were unable to demonstrate any effects of sodium amylobarbitone (90 mg), dexamphetamine (5 mg) or meprobamate (100 mg) on auditory flutter fusion threshold. However, the interruption rates of their auditory signal varied in the relatively large steps of ten interruptions per second (i.p.s.) so that small changes in the threshold might have escaped detection.

We have found that the auditory flutter fusion threshold was highly sensitive to centrally-acting drugs, and this communication reports the actions of amylobarbitone, chlorpromazine and perphenazine.

The technique was a modification of that used by Miller and Taylor[2]. A random noise signal, which could be interrupted at rates of between 1·5 and 275 i.p.s. (on–off ratio 9 : 1), was used at an intensity of 55 db (re. 0·0002 dynes/cm²). The interruptions were automatically switched on and off at intervals of 1 sec so that the signal, presented binaurally to the subject, consisted of alternating 1-sec periods of interrupted or continuous noise. For each test the starting interruption rate was 100 i.p.s. and then the signal was presented in a sequence of decreasing interruption rates. The critical descending auditory flutter fusion threshold was taken as the fastest interruption rate at which auditory flutter (that is, the interruptions) could be distinguished and below which consistent positive flutter responses were reported by the experimental subject.

Six normal healthy male subjects (aged 21–30 yr.) participated in each of the double blind cross-over trials. Subjects were allowed a light breakfast. The active compound (amylobarbitone—100 mg, or chlorpromazine—25 and 50 mg, or perphenazine—2 and 4 mg), or its placebo control, was administered by mouth between 9 and 10 a.m. at 7-day intervals. On each treatment day, three threshold determinations were made, at 5-min intervals, before treatment was administered and at 90 and 180 min later. Changes in the mean thresholds from the control values on the active and placebo treatments were compared using the method of analysis of variance for factorial designs and Student's two-tailed '*t*' test (Snedecor[5]).

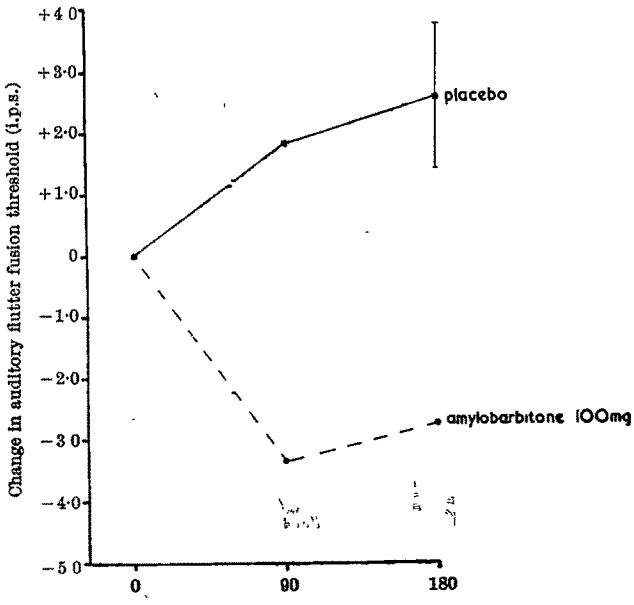

Fig. 1. The effect of amylobarbitone (100 mg) and placebo treatment on the descending auditory flutter fusion threshold. The changes in the mean thresholds are from those recorded before treatment (six subjects). ⊤ ■ ⊥, Standard error of the mean

The changes following amylobarbitone (100 mg) are illustrated in Fig. 1. The pretreatment mean thresholds were 42·93 i.p.s. for the placebo and 43·10 i.p.s. for the amylobarbitone treatment. The usual rise in the auditory flutter fusion threshold over the 180-min period on the placebo is seen (continuous line). After amylobarbitone (broken line), the threshold was lower than after the placebo both at 90 min (by 5·17 i.p.s.) and at 180 min (by 5·27 i.p.s.), and analysis showed that this depression was significant:

For the overall difference between placebo and amylobarbitone treatments effects, $F_{1,15} = 20{\cdot}03$, $P < 0{\cdot}001$.

For the difference between placebo and amylobarbitone treatment effects, at

90 min, $t_{15} = 3{\cdot}13$, $P < 0{\cdot}01$
and at 180 min, $t_{15} = 3{\cdot}19$, $P < 0{\cdot}01$.

The amylobarbitone induced depression thus developed within 90 min of oral administration and was maintained at about the same level for at least 180 min.

Chlorpromazine (25 and 50 mg) also produced statistically significant depression of the auditory flutter fusion threshold which was greater at 180 min than at 90 min. However, neither 2 mg nor 4 mg of perphenazine altered the auditory flutter fusion threshold, thus distinguishing between the actions of aliphatic and piperazine phenothiazine derivatives.

We thank Dr. P. Gorman and Mr. M. C. Martin of the Royal National Institute for the Deaf and Mr. P. M. G. Bell for their help.

Arylacethydroxamic Acids: a New Class of Potent Non-steroid Anti-inflammatory and Analgesic Substances

In recent years much effort has been directed to the search for non-steroid anti-inflammatory substances which can be used in the therapy of rheumatic diseases and related conditions[1]. This communication reports the finding that a chemical family hitherto unexplored in this respect, namely, the arylacethydroxamic acids, includes several substances endowed with considerable anti-inflammatory and analgesic properties, and also a remarkably low degree of toxicity. A particularly interesting compound in this series was 4-butoxy-3-methylphenylacethydroxamic acid (I). In a comparative investigation with known antiphlogistic compounds, using the Benitz and Hall carrageenin-induced abscess test in rats[2], compound (I), in exactly the same dose, proved only slightly less active (*c.* half) than phenylbutazone (1,2-diphenyl-3,5-diketo-4-butylpyrazolidine), definitely more active than 'Ibufenac' (*p*-isobutylphenylacetic acid), and considerably more so than aspirin. The activity shown by compound (I) at the high dosage of 1 g/kg was as intense as that of the maximum tolerated dose of phenylbutazone (400 mg/kg) and considerably more so than that (10 mg/kg) of 'Indomethacin' (1-*p*-chlorobenzoyl-5-methoxyindolyl-3-acetic acid), which is the most efficient non-steroid antiphlogistic substance known so far. Compound (I) was also strongly active in the carrageenin-induced granuloma test in rats, whereas phenylbutazone and aspirin are known to behave poorly in this type of assay[3].

(I)

(II)

Analgesic activity, determined in mice by means of Blake's test involving an electric stimulus[4], indicated that compound (I) was considerably more effective than the non-morphinic reference analgesics: the 50 per cent effective doses, measured after 90 min, were:

Compound (I)	18 mg/kg
'Ibufenac'	76 mg/kg
Acetophenetidine	103 mg/kg
Aminopyrine	109 mg/kg
Antipyrine	115 mg/kg
Aspirin	160 mg/kg

Comparative determination of acute toxicity in mice[5] with known anti-inflammatory agents gave the following figures for the 50 per cent lethal dose:

Compound (I)	1,800 mg/kg
Aspirin	1,100 mg/kg
Phenylbutazone	290 mg/kg
'Indomethacin'	26 mg/kg

Chronic oral toxicity tests performed in compound (I) in both rats and dogs produced no signs of toxicity at 125 mg/kg and per day.

The relationships between chemical structure and pharmacodynamic activity are evidenced in the data given in Table 1 for compounds chosen from among several hundred investigated.

Table 1

	Activity	
	Anti-inflammatory	Analgesic
4-Butoxy-3-methylphenylacethydroxamic acid (I)	++++	++++
4-Butoxyphenylacethydroxamic acid	++++	++++
4-Butoxy-2,3-dimethylphenylacethydroxamic acid	−	
4-Butoxy-5-isopropyl-2-methylphenylacethydroxamic acid	−	
4-Propoxyphenylacethydroxamic acid	+++	+++
4-Isopropoxyphenylacethydroxamic acid	+	
4-Amyloxyphenylacethydroxamic acid	±	
4-*Cyclo*pentyloxyphenylacethydroxamic acid	−	++
4-*Cyclo*hexyloxyphenylacethydroxamic acid	+	++
4-Propylphenylacethydroxamic acid	−	
4-Isobutylphenylacethydroxamic acid	++	
4-Butylphenylacethydroxamic acid	±	
4-Amylphenylacethydroxamic acid	−	
4-*Cyclo*hexylphenylacethydroxamic acid	−	+
4-Butoxyphenylacetic acid	−	−
4-Isobutoxyphenylacetic acid	−	−
4-Butoxyphenylacetamide (II)	−	++++
4-Butoxy-3-methylphenylacetamide	−	++++

The most interesting features to emerge from Table 1 are: (*a*) the complete disappearance of anti-inflammatory activity encountered in passing from 4-butoxyphenylacethydroxamic acid to 4-butoxyphenylacetic acid itself, thus pointing to a specific influence on the part of the hydroxamic acid function; (*b*) the discrepancy observed between the anti-inflammatory and analgesic activities—an extreme example being 4-butoxyphenylacetamide (II), the total inactivity of which as an anti-inflammatory agent contrasts strikingly with its remarkable analgesic potency, which is roughly the same as that of compound (I) (its 50 per cent effective dose being 17 mg/kg); 4-butoxyphenylacetamide, and 4-butoxyphenylacethydroxamic acid, also show antipyretic effects (in rabbits in a state of hyperthermia induced by injection of antityphoid vaccine TAB) comparable with that of aspirin; (*c*) the close dependence of anti-inflammatory activity on the number, nature, and site of the substituents on the aryl nucleus, a striking example being the absence of activity of 4-butoxy-2,3-dimethylphenylacethydroxamic acid, as compared with the outstanding activity of its lower homologue, compound (I). Further replacement of the nuclear methyl group in (I) by bromine, chlorine or fluorine results in comparably active compounds.

It is doubtless relevant to the mechanism of the anti-inflammatory action of compound (I) and its homologues that, on one hand, adrenalectomy inhibits their effects and, on the other hand, investigations made in rats with carbon-14-labelled 4-butoxyphenylacethydroxamic acid showed high levels of radioactivity in the adrenals.

Compounds (I) and (II) are both undergoing clinical trial.

PHYSIOLOGY

Athletic Performance at High Altitude

OWING to the lower partial pressure of oxygen the maximum oxygen intake of acclimatized adults at high altitude is less than the sea-level value. The reduction in the maximum oxygen intake at the 7,500 ft. altitude of Mexico City, where the 1968 Olympic Games are to be held, is expected to be 8 per cent following the trend of experiments made in the Himalayas[1]. From this result it has been predicted that the times for the running events at Mexico City would be 8 per cent longer than the expected sea-level times[2] except for the shorter events where the oxygen requirement could be covered anaerobically.

Pugh[2] compared the results of the 1955, Mexico City, Pan-American Games, with the results of the 1956 Melbourne Olympic Games and found a linear relationship between the increase in time and the logarithm of the distance of the race. The increase varied from 2·6 per cent for the 800 m event to 14·9 per cent for the 10,000 m event. This comparison, however, does not take into account the generally lower standard of performance of the athletes who were eligible to compete in the Pan-American games when compared with the standard of the athletes who competed in the Olympic Games.

Table 1. COMPARISON OF HIGH-ALTITUDE AND SEA-LEVEL PERFORMANCES

Event and athlete	Mexico City time	Best sea-level time (1954–1955)	Percentage increase in time
400 m			
Jones	45 4	46·4	−2·2
Lea	45 6	46·3	−1·5
Mashburn	46·3	46·1	+0 4
800 m			
Sowell	1 : 49·7	1 : 48·3	1·3
Spurrier	1 : 50 0	1 : 46·8*	3·0
Sandoval	1 : 52·4	1 : 50·9	1·4
1,500 m			
Miranda	3 : 53·2	3 : 53·8	−0·3
Santee	3 : 53·2	3 : 42·8	4·7
Dwyer	3 : 55·8	3 : 45·4*	4·6
5,000 m			
Suarez	15 : 30·6	14 : 26·2	7·4
Ashenfelter	15 : 31·4	14 : 42·2*	5·6
Correa	15 : 39 2	14 : 42·2	6·5
10,000 m			
Suarez	32 : 42·6	30 : 30·0	7·2
Sanchez	33 : 00 4	Not available	–
Correa	33 : 42·6	31 : 41·0	6·4

* Time adjusted from the equivalent "English" distance.

A better method of checking the decrement in performance at Mexico City is to compare the times of the athletes placed in the 1955 Pan-American Games events[3] with their best sea-level times for the years 1954[4] and 1955[3] (Table 1). The percentage difference in time for each athlete was calculated and the mean for each event plotted against the distance of the race (Fig. 1). The 100 m and 200 m events were excluded as wind conditions can considerably affect the best recorded times of the athletes concerned.

Table 2. DECREMENT IN PERFORMANCES

Distance	Observed mean percentage decrement	Calculated percentage decrement from equation
400 m	−1·1	–
800 m	1·9	1·95
1,500 m	3·0	3·20
3,000 m	–	4·96
5,000 m	6 5	6·14
10,000 m	6·8	6·97

The increase in the times for the distance events are less than those calculated previously and range from 1·9 per cent for the 800 m to 6·8 per cent for the 10,000 m (Table 2). The 400 m runners at Mexico City seem to have been assisted by the low aerodynamic drag at the high altitude; their times were reduced by an average of 1·1 per cent.

An exponential curve was fitted to the points from 800 m to 10,000 m by minimizing the squares of the differences between the observed mean decrements and the calculated decrements. The equation for this curve was

$$P = 7{\cdot}1\,(1 - e^{-0{\cdot}00040D})$$

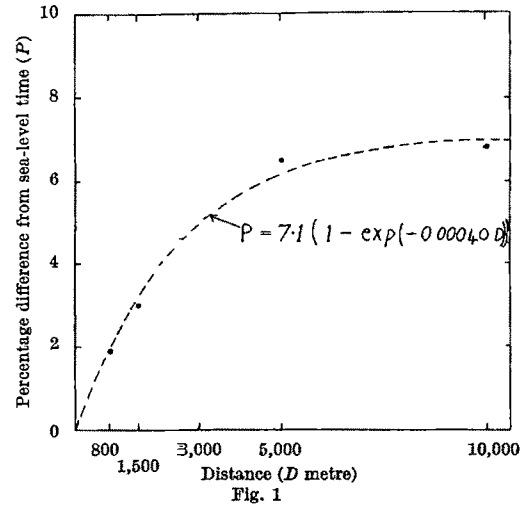

Fig. 1

where P is the percentage increase in time taken to run the distance in metres, D, at 7,500 ft. altitude. This equation indicates that the increase in time taken to run an event approaches the value of 7·1 per cent for the very long races. This is in excellent agreement with Pugh's estimate of 8 per cent based on maximum exercise tests as some assistance is probably gained from the lower aerodynamic drag on an athlete at an altitude of 7,500 ft.

Tolerance of Chickens to Thiabendazole

THIABENDAZOLE, a broad-spectrum anthelmintic[1,2], is well tolerated by mice, rats and rabbits, with LD_{50} values exceeding 3·1 g/kg in oral acute toxicity experiments[3]. Furthermore, rats and dogs tolerated the drug quite well in chronic toxicity experiments[3].

Recent unpublished experiments with adult chickens fed thiabendazole continuously for 3 weeks revealed that a level of 0·1 per cent in the diet has no effect on reproduction, egg production or feed intake, but that levels exceeding 0·2 per cent produced lower values for all three criteria. In addition, the birds fed these high levels of thiabendazole appeared anaemic and about 7 per cent mortality occurred at the 0·2 per cent level with progressively higher mortality at higher drug levels. Post-mortem examination of the hens revealed haemorrhaging throughout most internal organs, but particularly at the ovary. Haematological data were obtained in a series of experiments in which thiabendazole was fed for 21 days to

* Mean ± standard error of the mean.

hens. The data show that haemoglobin and haematocrit values were markedly below normal in hens treated with 0·2 or 0·4 per cent thiabendazole, and this correlated with their pale appearance (Table 1). Sedimentation rates were elevated, but whole-blood clotting time and prothrombin clotting time showed no consistent change from the norm. However, it should be noted that whole-blood clotting time assays are subject to wide variability and many values are required to show a trend. Also, it should be pointed out that two birds sampled at the end of the second week on 0·4 per cent thiabendazole had clotting times exceeding 60 min, the cut-off time for the assay, and that one of the four birds sampled at the end of the third week had a whole-blood clotting time exceeding 60 min. When these data are considered with the mortality values and the post-mortem findings, there is an indication that blood clotting time may be influenced provided the drug level is 0·4 per cent or higher.

Most interesting was that the addition of 1 mg vitamin B_{12} per kg, 100 mg ascorbic acid per kg, and 20 mg menadione per kg diet containing 0·4 per cent thiabendazole counteracted the adverse effect of the drug on the haematological values (Table 1) of the hens. These birds at necropsy did not have the haemorrhages that were observed in those receiving the drug alone. As shown in Table 2, B_{12} and menadione, and not ascorbic acid, counteracted the adverse effect of thiabendazole on haemoglobin and haematocrit levels. Each vitamin alone, partially reversed the effect at the levels fed, and the addition of both vitamins to the diet completely overcame the adverse effect of 0·2 per cent (Table 2), as well as 0·4 per cent thiabendazole (Table 1).

In comparison to other species of animals in which thiabendazole is well tolerated, the adult female chicken appears to be more sensitive to the drug. Hens fed a diet containing 0·2 per cent thiabendazole consumed 80 mg thiabendazole per kg body-weight daily. This dose is about 0·5–0·33 of the amount required to produce a moderate anaemia in dogs[3]. Single oral doses of 50 mg/kg have proved highly efficacious in roundworm infections in those mammals for which the drug is recommended, so there is an adequate safety margin for thiabendazole. We have investigated the effect of thiabendazole when fed to chickens to 6 weeks of age and find that they tolerate (for growth) about 0·1 per cent of the drug in the diet and have normal haemoglobin levels.

Investigations in progress are designed to reveal the maximum tolerated level of thiabendazole in the hens' diet without effect on their haematology, which is estimated, from the data in Tables 1 and 2, to be in the range of 0·05–0·1 per cent thiabendazole in the diet. In addition, investigations are at present in progress to reveal the mode of action between thiabendazole and vitamins B_{12} and K, and the possible interaction of the endocrines on the drug–vitamin relationship.

Effect of Removing the Neocortex on the Response to Repeated Sensory Stimulation of Neurones in the Mid-brain

THE response of a high proportion of cells in the superior colliculus and subjacent structures (tecto-tegmental region) of the rabbit mid-brain gradually wanes when a sensory stimulus is repeatedly presented at rates between 1 per sec and 1/4 per sec[1,2]. The number of stimuli required to bring about attenuation of response (habituation) varies from cell to cell and, for a given cell, from stimulus to stimulus, but lies between two and fifty presentations. The response may be restored by withholding the stimulus for some 20 sec or more and presenting it again (recovery by time lapse). In the experiments on which these observations are based, the animals were anaesthetized with urethane-pentobarbitone and the recording micro-electrodes directed to the mid-brain by a hole drilled in the skull. Thus apart from the tracks made by the electrodes the cerebral cortex was intact.

The tecto-tegmental region of mammals receives an extensive innervation from the neo-cortex[3–5] and a question that remains is whether this structure must be present for habituation to occur in the tecto-tegmental cells. This question is answered in the experiments described here.

Five rabbits (weights 2·5–3·5 kg) were used. The solution and dosage of anaesthetic were the same as in our previous experiments[1,2]. Each animal was mounted in a stereotaxic frame and the roof of the cranial cavity removed. The neo-cortex lateral to the rhinal fissure was removed by aspiration, gelatin sponge being used to control haemorrhage. Care was taken to avoid damage to the optic nerves and tracts. When bleeding stopped, a 4 per cent aqueous solution of agar was poured over the brain to reduce cardiovascular and respiratory pulsations. The pupil of the right eye was then dilated and the eye refracted as before. The quadrigeminal bodies could be seen clearly through the solidified agar and the electrode was lowered into the left superior colliculus under direct vision. All penetrations were taken to a depth of 10 mm below the surface of the colliculus. At the end of an experiment the brain was fixed *in situ* by removing the head and immersing it in 10 per cent formol saline. The brain was afterwards removed, examined macroscopically to ensure that the optic nerves, chiasma and tracts were intact, and then sectioned and stained for histological examination.

The photic stimuli consisted of stationary and moving spots of light projected on to a screen. Acoustic stimuli consisted of tones and clicks and the tactile stimulus was air blown through a rubber tube over restricted regions of the skin. During the experiment the intensity of background illumination varied from 0·6 to 1·0 ft.-L.

Spontaneous impulse activity was usually brisk some 6–8 h after decortication. Before this, the mid-brain was relatively quiet and little spontaneous or evoked activity could be detected.

One hundred and ten units were studied of which 74 responded to at least one sensory stimulus. Functional lamination of the units was more marked in these preparations than in those with the cerebral cortex intact, the majority of units responding to photic stimuli lying between the surface and a depth of 2·3 mm (that is, within stratum griseum superficiale and stratum opticum)

and the majority of those responding to acoustic and to tactile stimuli lying between 3·0 and 10·0 mm below the surface of the tectum. Between 2·3 and 3·0 mm there was a transitional zone in which a few cells (four) could be activated by both photic and acoustic stimuli.

We used the same criteria for habituation as before, namely, that the response should wane within fifty presentations of a stimulus delivered at a rate of between 1 per sec and 1 per 4 sec. We were able to hold for the necessary length of time only fifty-one of the units which responded to sensory stimulation. Habituation was observed in nineteen of them and these units were not restricted to any particular depth below the surface of the tectum. The time-course of this process was not different from that observed previously in intact animals. Recovery by time-lapse could be demonstrated in all units whose response to a stimulus waned and is illustrated in Fig. 1. This unit responded with a burst of impulses when a spot of light was turned on in the middle of its receptive field. The stimulus (1 sec duration) was presented at the rate of 1 per 2 sec. Record 1 shows the response (five spikes) to the first stimulus of the series which was begun after a period of 60 sec, during which no stimuli were presented. Only one spike was evoked by the fourth stimulus (record 4) and there was no response to the next six stimuli. After the tenth stimulus presentation (record 10) the stimulus was withheld for 40 sec following which it elicited a burst (five spikes) of activity (record 11).

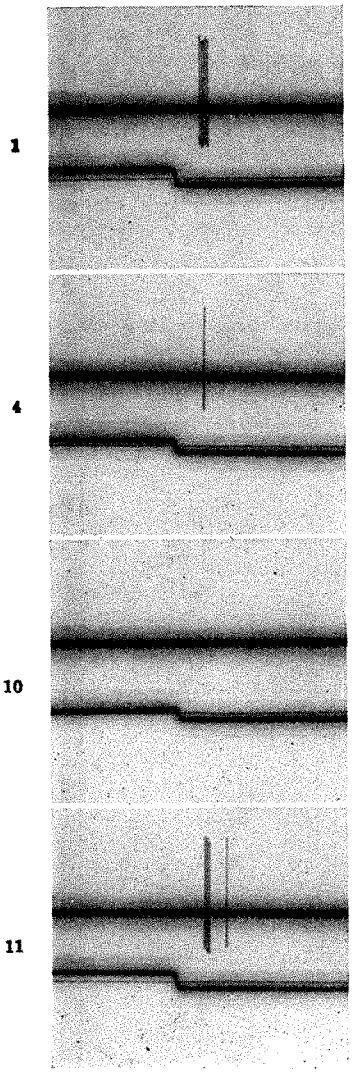

Fig. 1. Attenuation of response to repeated presentation of a spot of light at the centre of a unit's receptive field. When spikes are present they are shown on the upper trace of each record, upward deflexion being positive. A photocell placed in front of the light source was used to signal light onset, which is indicated by a downward displacement of the lower trace. Read records from left to right. Stimulus (intensity 15 ft.-*L*, 2° diameter, duration 1 sec) presented at rate of 1 per 2 sec. Record 1 shows the response (five spikes) to the first stimulus of the series presented after an inter-stimulus interval of 60 sec. Responses to fourth (record 4) and tenth stimuli (record 10) of the series are shown. An interval of 40 sec intervened between stimuli 10 and 11 and the response to the eleventh stimulus (five spikes) is shown (record 11). This unit was recorded at a depth of 1·3 mm below surface of the left superior colliculus. Scale 0·5 sec

At post-mortem it was found that the neo-cortex had been removed bilaterally in all animals and a varying amount of pyriform cortex, medial to the rhinal fissure, remained.

Effect of Urgocyton on Capillary Permeability in Rabbits

IT has been reported that urgocyton, a non-coagulable and fluorescent protein (polypeptide) prepared from ox liver, markedly inhibits the bradykinin-destroying activity of haemolysed blood cells and also, to some extent, of plasma[1].

It is known that the intradermal injection of bradykinin in a guinea-pig with circulating blue dye regularly increases the passage of dye through the blood vessels and produces skin lesions of an intense blue colour. This response can also be elicited in rabbit skin[2].

We have investigated the effect of intradermal injections of urgocyton in rabbit skin, bearing in mind that inhibition of kininase-activity *in loco* might liberate bradykinin, which could then be demonstrated by the blue skin lesion produced in rabbits with circulating blue dye.

White land rabbits, weighing 1·8–2·5 kg, were used. The dorsal and, in some animals, also the abdominal skin was shaved with an electric razor 24 h before the tests. All materials to be tested were dissolved in saline and injected intradermally in amounts of 0·1 ml. Injection of saline (0·1 ml.) was used in the control animals. Crystalline bovine albumin and crystalline soy bean inhibitor were used to test the unspecific response to proteins.

Ten to 30 min after the intradermal injection, 1 ml./kg of 1 per cent Evans blue was injected intravenously.

Urgocyton from two different batches prepared as described previously[1] was administered in doses ranging from 0·5 to 0·005 mg.

For comparison, synthetic bradykinin or kallidin (kindly supplied by Sandoz A.G., Basle) was used and injected in amounts of 0·001 or 0·002 mg. Haemolysate prepared as described previously[1] and carboxypeptidase were used as sources of bradykinin-destroying enzymes. Crystalline carboxypeptidase *B* (Sigma Chemical Company) was tested for its bradykinin-destroying property using the rat uterus method[1]. It was found that 0·004 mg of this enzyme degraded bradykinin as fast as 1 ml. of the haemolysate.

Two to 3 min after the injection of Evans blue, visible blueing appeared at the sites where urgocyton had been

injected and increased in size in the next 45–60 min. The response given is the mean of two perpendicular diameters of the blue area after 30 min. In twenty-five of twenty-seven animals tested, intradermal injection of urgocyton provoked the extrusion of blue colour at the site of the injection. The two failures probably resulted from faulty technique. No difference in the response with the two different batches of urgocyton has been seen. The response to 0·5 mg urgocyton varied in different animals from 4 to 15 mm and corresponded to that of 0·002 mg bradykinin or kallidin (the response to these synthetic kinins was identical). The size of the response to 0·5 mg albumin, 0·5 mg soy bean trypsin inhibitor, and saline never exceeded 3 mm. There was little difference between the dorsal and abdominal regions of the skin in the reaction to intradermal injections of urgocyton or bradykinin. The smallest dose of urgocyton (in four animals) which gave a blue spot greater than that of saline was 0·005 mg.

The effect of urgocyton could be prevented by treatment of the animal beforehand with haemolysed blood injected intravenously. To demonstrate this, 3–5 ml. of blood was removed by cardiac puncture from each animal 24 h before the skin tests. The blood was kept at −20° C and became haemolysed when warmed to room temperature immediately before the injections. Intradermal injections of urgocyton, and of bradykinin or kallidin, were then made as described previously, on the dorsal skin of the rabbits. Ten min later, Evans blue was injected intravenously and blueing appeared at the sites of the intradermal injections. Thirty min after the injection of the dye, haemolysed blood was injected intravenously (each animal was given haemolysate from its own blood). Ten min after this injection, intradermal injections of urgocyton, bradykinin or kallidin were made on the abdominal skin of the animal.

Two ml. of haemolysed blood were given to each of six rabbits. In four of these, the reactions of the abdominal skin were identical with those on the dorsal skin. In two animals, however, no reactions appeared on the abdomen. When 4 ml. of haemolysed blood was injected intravenously, complete inhibition of the reaction due to intradermal injection of 0·5 mg urgocyton and 0·002 mg of bradykinin or kallidin on the abdominal skin in five of the five test animals was seen. In another eight animals, previous injection of 4 ml. of haemolysate completely prevented the reaction to intradermal injection in the dorsal skin of 0·5 mg urgocyton and of 0·002 mg of bradykinin, respectively (no abdominal injections were made in these animals).

No similar effect, however, could be accomplished by injecting carboxypeptidase *B* intravenously in eight animals in amounts corresponding to 4 ml. of haemolysate.

The demonstration that urgocyton provoked increased capillary permeability in rabbit skin by intradermal administration is interesting. The abolition of this effect by intravenous injection of haemolysate containing kininase might suggest that urgocyton works through a bradykinin effect elicited by inhibition of local kininases.

The failure of carboxypeptidase *B* to imitate the inhibitory effect of haemolysate is surprising, but it may be explained by one of the following possibilities: (1) The effect of urgocyton on the capillary permeability is not due to the neutralization of kininase. (2) Carboxypeptidase *B* is not capable of penetrating the capillaries. (3) The haemolysate contains other kininase(s) than carboxypeptidase *B*.

Reduced Diphosphopyridine Nucleotide-dependent Diaphorase in Foetal, Newborn and Adult Cattle

ABORTIONS in cattle have been reported to occur as a result of nitrate poisoning[1]. Although the exact cause of death has not been elucidated, anoxia due to methaemoglobinaemia is believed to be responsible. Recently a transient deficiency of reduced diphosphopyridine nucleotide (DPNH)-dependent diaphorase in infants has been demonstrated, and it has been suggested that this may be a major cause of the increased susceptibility of newly born babies and animals to acquired methaemoglobinaemia[2]. It was also suggested that even lower enzyme activity would be encountered in foetal erythrocytes[2]. The present investigation was undertaken to determine whether the abortions occurring in nitrate poisoning of cattle could be related to foetal erythrocyte diaphorase levels.

Samples were taken from Holstein-Fresian cattle during slaughter, from foetal calves by cardiac puncture and newborn animals by venipuncture into acid-citrate-dextrose (ACD) to which 0·25 per cent sodium chloride had been added to increase the osmotic strength to a level more nearly isotonic with erythrocytes. DPNH-dependent diaphorase was measured by the method of Scott[3] incorporating the more prolonged incubation with sodium nitrite recommended by Ross[2]. All assays were carried out in a Gilford model 2,000 multiple absorbance recorder at room temperature and only the initial reaction rates were considered. The unit of activity has been defined by Scott[3].

The results are summarized in Fig. 1. The mean erythrocyte diaphorase level of thirty-nine adult cows was $22{\cdot}0 \pm 4{\cdot}6$ units, while that of foetuses was $169 \pm 25{\cdot}8$ units, and of eight newborn animals was 177 ± 51 units.

It is apparent that there are marked differences in the levels of methaemoglobin diaphorase in the newborn calf and the newborn baby. Average enzyme activity of the newborn baby is significantly lower than that of the red cells of an adult human being[2]; that of the unborn and newborn calf is spectacularly higher than that of adult cattle. Nitrite is a normal intermediate in the metabolism of nitrates by the bacterial flora of the rumen of cattle[4]. It is known that bovine foetal haemoglobin is much more susceptible to oxidation to methaemoglobin by nitrite than is bovine adult haemoglobin[5]. For these reasons the bovine foetus is an especially high risk with regard to the development of serious methaemoglobinaemia. An increase in the DPNH-dependent methaemoglobin diaphorase may represent an adaptation on the part of cattle to these special circumstances.

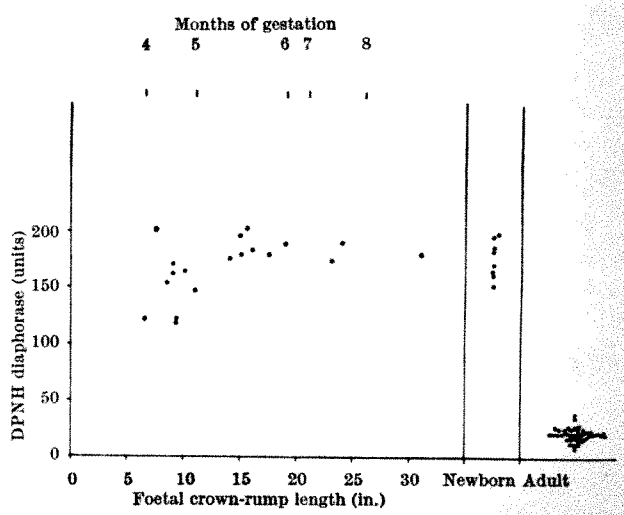

Fig. 1. DPNH-dependent diaphorase of foetal, newborn and adult cattle

It seems that the abortions resulting from nitrate poisoning in cattle are not related to a decrease in the level of DPNH-dependent diaphorase which is common to the entire species. However, we have not been able to examine individual foetuses, which were aborted as a result of nitrate poisoning, to rule out the possibility of a genetic polymorphism.

This investigation was supported in part by a U.S. Public Health Service research grant from the National Heart Institute.

BIOPHYSICS

Relationship of Ortho-cortex to the Crimp Wave in a Double-crimped Wool

THE cortex of a crimped Merino wool fibre comprises two hemi-cylinders, which differ in both chemical and physical properties. The form of the crimp wave is related to alternations in the positions of the two cortical components within the fibre—the ortho- and the para-cortex[1-4]. The ortho-cortex tends to lie on the convex aspect of the crimp wave and the para-cortex on the concave aspect.

The ortho-cortex can be demonstrated *inter alia* by dyeing with cupric ion in acidic nitrite solution[5].

Wool staples which have two clearly discernible staple crimp forms, one of short wave-length and the other of longer wave-length, occur in certain Merino wools from time to time. The question arises as to the alternations of the ortho- relative to the para-cortex, when the situation is complicated by the presence of two staple crimps.

An excellent example of this type of wool was received from the Western District of Victoria. The primary crimped form had 20–22 crimps/in. and the secondary had 6 crimps/in. The terms primary and secondary are used arbitrarily and purely for reference. A staple was dyed with cupric ions in acidic nitrite solution (1 per cent cupric sulphate in 1·5 per cent w/w aqueous sodium nitrite in 3 per cent acetic acid with a wool/liquor ratio of 1 : 120 or 1 : 150 for 10 min at 65–75° C). Ten fibres were withdrawn, of mean diameters ranging from 15μ to 27μ. These were thus removed from the staple environment and its forces, and cannot be assumed to have retained their intra-staple forms. However, the primary and secondary crimp forms were still clearly evident, and to allow examination by the microscope, the untensioned fibre was laid on a glass slide and a glass coverslip gently lowered on to it to hold the fibre in a single plane. The camera lucida image of the fibre with the position of the ortho-cortex inserted was traced by hand. Magnified lengths were correct, but the width was doubled for convenience in marking.

The alternations of the ortho-cortex showed two phases. In the first of these, the wave-length of the alternations was constant and in general was associated with a small-amplitude fibre crimp form. In the second, the wave-length was longer and variable and in general associated with abrupt bends in the fibre, which appeared to tally with the secondary crimp. Sometimes the abrupt form changed immediately back to alternations of the first phase; sometimes the abrupt form persisted for a much longer length, before the recovery to the first phase. Fig. 1 indicates two typical cases.

It therefore appears that whatever controls the regular alternation of the ortho-cortex may, by the interruption of its action, lead to the formation of the secondary type of crimp. The alternative may be that the periodic rate of alternation is constant, but the length-rate of growth shows spasmodic changes. Since the fibre axis of wool fibres tends to twist to and fro along its length with a period equal to the wave-length of the crimp form[6,7], it is possible that the abrupt bends may be related to peculiar effects of the axial twist. Unfortunately, measurement of axial twist is extremely difficult to carry out in wool fibres, because these are so sensitive to tensile and torsional forces and to relaxation of cohesive set, when the moisture content changes[7,8].

Crimp Form: a New Factor in Wool Science

WE have endeavoured to estimate the spatial configurations of single wool fibres by means of static and dynamic experiments in the decrimping region[1]. While some fleeces predominantly consist of helical shaped fibres, other fleeces are made up of almost perfectly sinusoidal fibres. Randomized assemblies prepared from the two extreme crimp types reveal strikingly different properties. One of the most outstanding results concerns the unique felting behaviour of wool fibres.

Under the influence of an external impressed force, assemblies of wool fibres in aqueous solution become highly entangled to form a dense mass or "felt". Although this property primarily arises from the unique surface structure of the fibre, no satisfactory explanation has been offered for the large variations that occur among different wools in their ability to felt. The factors to which these variations have most commonly been attributed include diameter, length and crimping. It can be demonstrated however, that these parameters are of little significance compared with crimp form.

Table 1

	Sample	Crimp configuration	Diameter of felt ball (cm)	Fibre diameter (μ)	Fibre length (cm)	No. of crimps (per cm)
A	Merino	Sinusoidal	2·15	22·1	11·4	4·5
B	Lincoln	Sinusoidal	2·24	40·0	20·3	0·35
C	South Down	Helix	3·42	30·0	12·8	3·6
D	Suffolk Down	Helix	3·74	30·4	12·0	4·4

Table 1 gives the various characteristics of four samples of wool, together with crimp form and felting results[2] (a small diameter for the felt ball indicates a high degree of felting). There are no marked differences in the frictional properties of the two sets of samples and it is clear that large variations in diameter, length and numbers of crimps have little influence on the felting results. The only consistent parameter is crimp form. Indeed, the felting of the helical fibres is so poor that individual fibres can be readily withdrawn from the large irregular balls (Fig. 1).

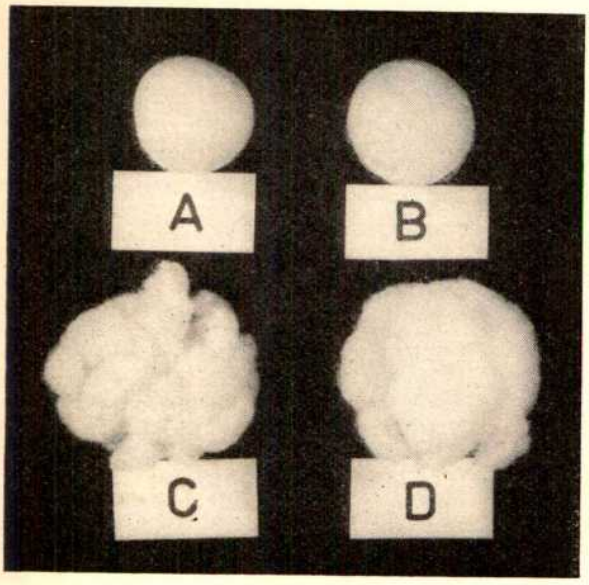

Fig. 1

The results cast considerable doubt on the traditional belief that fine fibres felt at a greater rate than coarse fibres. On the other hand, the results not only confirm some observations of Crewther and Dowling[3], who varied the rate of felting by modifying crimp form, but also offer a new explanation for the large variations in the felting properties of different wool types[4].

BIOLOGY

Uncoupling of Auxin-induced Protein Synthesis and Water Uptake by Kinetin

IT is generally recognized that water uptake, synthesis of protein, and respiration are intimately related activities by which the growth of cells and tissues are controlled. Protein synthesis has been implicated in the mechanism of water uptake, and it has been shown that substances which inhibit protein synthesis also inhibit water uptake[1]. Evidence has also been presented that auxin-induced increases in growth and water uptake are not only accompanied by a net increase in protein content[2,3], but are also dependent on the continual synthesis of new protein[4]. Kinetin has been shown to inhibit increases in longitudinal growth[5] and in water uptake[6] caused by auxin in etiolated pea stem sections; however, it causes marked thickening of the sections. This report presents evidence to support the thesis that protein synthesis is even more intense during this kinetin inhibition of auxin-induced growth.

Pea (*Pisum sativum* var. 'Alderman') seedlings were grown in the dark for 8–9 days at 25° C, during which time they were subjected to various periods of red light. 10-mm sections cut from just below the "crook" region were used for the experiments and five such sections were made of each sample. The isolated sections were floated on 6 ml. of sucrose solution in Petri dishes with or without added auxin and/or kinetin, and were incubated in the dark for 24 h. The growth was assessed at regular intervals and the nitrogen content estimated by the routine micro-kjeldahl method[7].

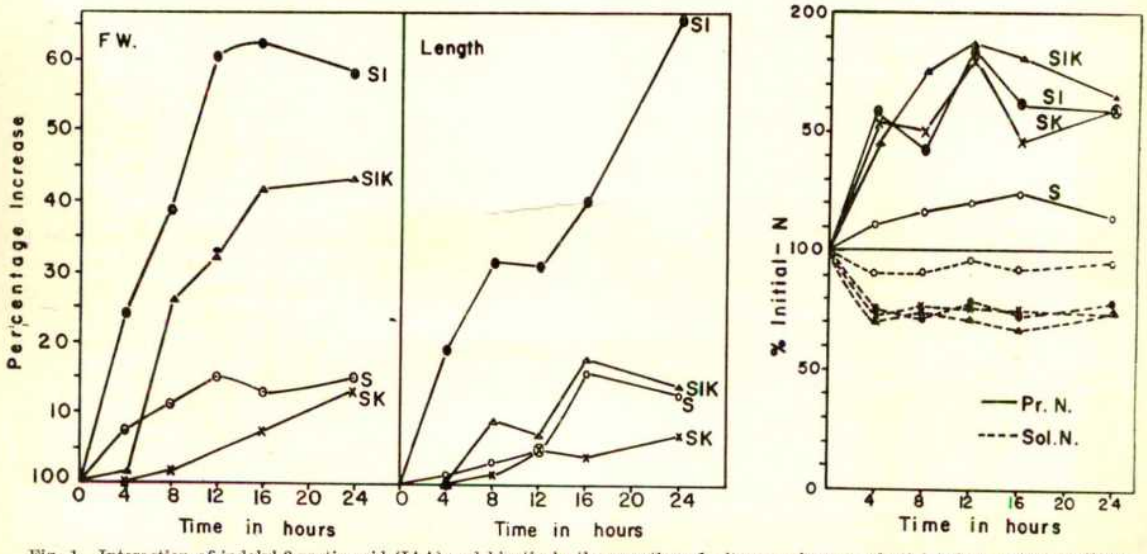

Fig. 1. Interaction of indolyl-3-acetic acid (IAA) and kinetin in the growth and nitrogen changes of etiolated pea stem sections. *S*, Sucrose 2 per cent; *SI*, 2 per cent sucrose + 1 p.p.m. IAA; *SK*, 2 per cent sucrose + 10 p.p.m. kinetin; *SIK*, 2 per cent sucrose + 1 p.p.m. IAA + 10 p.p.m. kinetin

Our findings confirm those of Katsumi[6] in that we observed that kinetin inhibits longitudinal growth and uptake of water in sections floated on sucrose alone and, furthermore, suppresses indolyl-3-acetic acid-promoted increases in length and green weight. The inhibitory effect on the former was found to be more marked than on the latter. Exogenous indolyl-3-acetic acid and kinetin, supplied individually, brought about almost identical changes in protein synthesis and further increase was noticed in sections which received both indolyl-3-acetic acid and kinetin. An optimum protein content was reached after about 12 h of growth in each case. Protein changes in indolyl-3-acetic acid-treated sections closely paralleled changes in longitudinal growth and green weight. It will be seen, however, that although the increase in length induced by indolyl-3-acetic acid was almost quantitatively reversed by kinetin and, moreover, the growth of control sections kept on sucrose was inhibited, the increase in protein content was far greater.

We conclude from these results that there may be no direct relationship between the observed enhancement of protein synthesis and the growth effects of auxin. Kinetin seems to act as an uncoupler of auxin-induced protein synthesis and water uptake. This suggests that auxin-dependent water uptake may be related to some metabolic activity other than to the synthesis of protein, but still associated with growth. The correlation usually made between protein synthesis and water uptake is most surprising. In theory, one molecule of water is released for each peptide bond formed during the synthesis of the protein molecule. Furthermore, coiling of the peptide chain would lock up various hydration sites[8] with the result that the osmotic concentration of the cell sap would decline. Indeed, there are examples on record which indicate that water uptake may occur in tissues showing a net decline in protein synthesis[9].

Chromosome Number of a Sub-Antarctic *Rubus*

Rubus geoides from the southern hemisphere is a creeping form of bramble with simple, glossy leaves and hermaphrodite flowers. It occurs in Patagonia and in the Falkland Islands, where it is harvested locally for the red raspberry-like fruits. This species can be considered to be the southern equivalent of the northern hemisphere circumpolar species of creeping diploid *Rubus arcticus*. *R. geoides* was considered of possible interest for raspberry and blackberry breeding in Scotland because of its hardiness, lack of thorns, and its ability to produce fruits under windy and extreme climatic conditions. Plants raised from seeds received from Patagonia have grown well both indoors and outdoors in the east of Scotland, although its leaves are subject to mildew when kept in a poorly ventilated glasshouse and its flowering has been sparse.

The somatic chromosome number, previously unknown, has now been determined from root-tips of two plants[1]. Both these were tetraploid ($2n = 28$) and within the complement the contracted chromosomes vary slightly in size (Fig. 1). The complement includes only a single satellited chromosome, whereas in tetraploid species of the true blackberries (*Eubati*) from Scotland there may

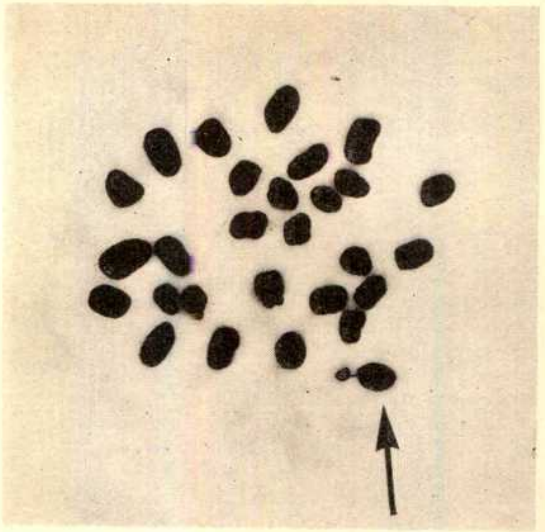

Fig. 1. Somatic chromosomes of *Rubus geoides* ($2n = 28$). (× 6,552). Note the occurrence of only one satellited chromosome (arrowed) in the tetraploid complement

be as many as five satellites present or two as in the diploid raspberry (*R. idaeus*)[3]. We have postulated[2] that in *Rubus* an increase in satellite number may have an adaptive function in relation to climate, especially in association with cooler growing conditions; but this does not appear to be so for *R. geoides*. Furthermore, the occurrence of only one satellited chromosome in a tetraploid species suggests amphiplasty, which has already been found by Heslop-Harrison[3] in *Rubus* and confirmed by Tun[4] for ribes species hybrids; thus *R. geoides* may be a true breeding species hybrid. In support of this, more flavonoid components are found to be present than in the two primary northern European diploid species of *Rubus*.

That *R. geoides* is a tetraploid has advantages for the breeder for it will probably readily hybridize through its diploid gametes. Furthermore, owing to wide geographical isolation from *R. idaeus* it is possible that such hybrids between these two species will show strong heterosis.

Phosphatidyl Carnitine: a Possible Intermediate in the Biosynthesis of Phosphatidyl β-Methylcholine in *Phormia regina* (Meigen)

CARNITINE can replace the dietary choline, otherwise essential, when *Phormia regina* larvae are reared on a chemically defined diet[1,2]. When this substitution is made, β-methylcholine almost completely replaces choline in the lecithin of the larva[3,4]. Similar results have been obtained with the house fly, *Musca domestica* Linnaeus[5]. γ-Butyrobetaine can also substitute for choline in the diet[2], giving rise to phosphatidyl β-methylcholine[6]. Recent investigations by Hodgson and Dauterman[7] have demonstrated that trimethyl-(3-hydroxypropyl) ammonium acetate (TMAA) inhibits the growth of *P. regina* larvae when the

choline of the diet is replaced by carnitine or γ-butyrobetaine but does not when choline is present. Thus, it would appear to inhibit one of the metabolic reactions between carnitine or γ-butyrobetaine and the β-methylcholine moiety of phosphatidyl β-methylcholine.

The carnitine, labelled with carbon-14 in the methyl groups, used in the present investigation was synthesized according to the method of Mazzetti *et al.*[8], and the purity established by co-chromatography with authentic carnitine. The melting point of the synthesized material was 142° C. β-Methylcholine was prepared by the hydrolysis of acetyl β-methylcholine and recrystallization from *n*-butanol–ether.

P. regina larvae were grown in axenic culture on a chemically defined diet according to McGinnis *et al.*[9], as modified by Hodgson *et al.*[2]. In each experiment, carbon-14-D,L-carnitine was included in one set of flasks at a concentration of 0·2 mg/ml. of diet and carbon-14-D,L-carnitine and TMAA at concentrations of 0·2 and 0·17 mg in another. Third instar larvae were removed on the seventh day after inoculation, homogenized and extracted twice with 10 per cent trichloroacetic acid. The residue was extracted three times with chloroform–methanol (2 : 1, v/v). Trichloroacetic acid was removed from the water by washing with ether. Water-soluble contaminants were removed from the lipid layer by washing with 50 per cent methanol until no further radioactivity appeared in the upper layer. After hydrolysis in 6 N hydrochloric acid for 12 h at 110° C, β-methylcholine and carnitine were separated by paper chromatography and the radioactive spots detected by scanning in a 'Vanguard 4 pi' strip scanner. Spots were identified by co-chromatography in the following solvents: ethanol–ammonia, 95 : 5; *n*-butanol–water–ethanol–ammonia, 8 : 3 : 2 : 1; *n*-propanol–ammonia–water, 85 : 5 : 10.

Chromatograms of the hydrolysate of the whole lipid extract of larvae fed carbon-14-carnitine showed only one radioactive spot corresponding to β-methylcholine. This confirms the findings of Bieber *et al.*[3,4]. When carbon-14-carnitine and TMAA are fed, however, two radioactive compounds, β-methylcholine and carnitine, can be found in the lipid hydrolysate (Fig. 1).

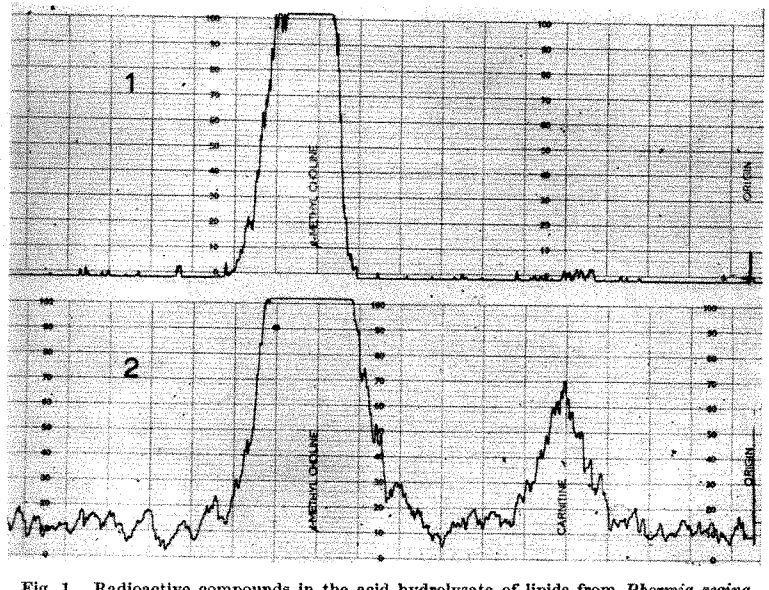

Fig. 1. Radioactive compounds in the acid hydrolysate of lipids from *Phormia regina* larvae fed methyl-carbon-14-carnitine. Hydrolysis products were separated by ascending paper chromatography in ethanol–ammonia and radioactive areas located by scanning in a 'Vanguard 4 pi' strip scanner. 1 is derived from larvae fed methyl-carbon-14-carnitine and 2 from larvae fed methyl-(3-hydroxypropyl) ammonium acetate

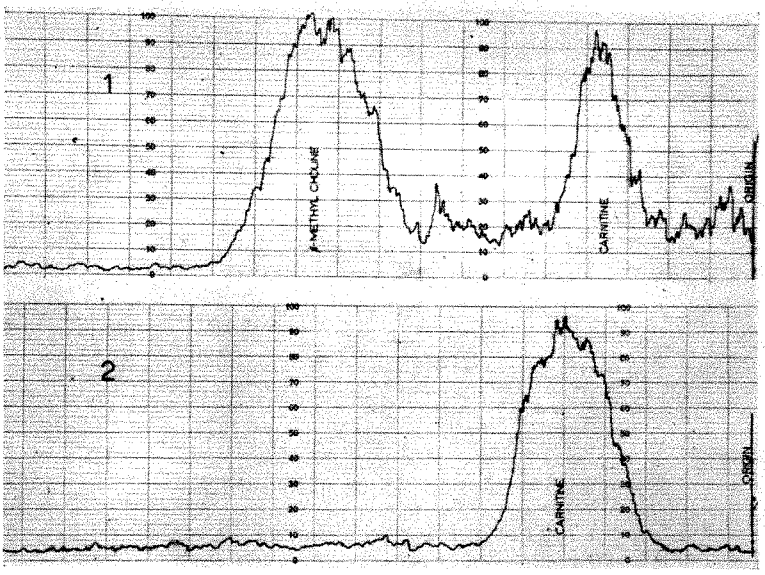

Fig. 2. Radioactive compounds in the acid hydrolysates of phospholipids from *Phormia regina* larvae fed methyl-carbon-14-carnitine and trimethyl-(3-hydroxypropyl) ammonium acetate. Hydrolysis products were separated by ascending paper chromatography in ethanol–ammonia and radioactive areas located by scanning in a 'Vanguard 4 pi' strip scanner. 1 is derived from the first radioactive peak from a silicic acid–'Hyflo Super-Cel' column. 2 is derived from the phospholipid eluted from DEAE-cellulose columns with chloroform–methanol (7 : 1) when the first peak from silicic acid–'Hyflo Super-Cel' columns is rechromatographed

Phospholipids were separated on silicic acid–'Hyflo Super-Cel' columns by methods previously used with this organism[10]. Three radioactive peaks were eluted from the lipids of larvae fed carbon-14-carnitine and TMAA, the first and largest peak containing, on hydrolysis, both carnitine and β-methylcholine while the last two contained only β-methylcholine. The first peak was rechromatographed on DEAE-cellulose according to the method of Rouser *et al.*[11], and a peak, eluted with chloroform–methanol (7 : 1, v/v), proved, on hydrolysis, to contain only carnitine (Fig. 2).

Similar experiments using carbon-14-carnitine without TMAA yielded β-methylcholine as the sole radioactive hydrolysis product in all three peaks separated on silicic acid–'Hyflo Super-Cel' columns.

The water layers, both with and without the inhibitor, were identical, four radioactive peaks being separated by paper chromatography. The hydrolysed water layer showed two radioactive compounds, carnitine and β-methylcholine, in a ratio of approximately 95 to 5.

The results reported here indicate that carnitine is incorporated into a lipid soluble compound before decarboxylation to the β-methylcholine of phosphatidyl β-methylcholine. The available evidence supports the hypothesis that this compound is phosphatidyl carnitine. The inhibitor, TMAA, previously implicated[6] on nutritional grounds in the decarboxylation of carnitine, causes this lipid soluble carnitine derivative to accumulate to the point where detection is possible.

The suggestion was considered that contamination of phospholipid fractions with an acyl carnitine had occurred. Palmitylcarnitine synthesized by the method of Bremer[12] was compared by thin-layer chromatography with the lipid extract obtained after feeding carbon-14-carnitine and TMAA

and was shown not to correspond to any of the radioactive spots. Short chain acyl carnitines would not be expected to contaminate washed lipid extracts.

The observation that TMAA is incorporated into a phospholipid may be of importance in elucidation of the mechanism of its inhibitory action. Thin-layer chromatography on silica gel *G* using chloroform–methanol–acetic acid–water (25 : 15 : 4 : 2) indicates that several of the unusual phospholipids formed when dietary choline is replaced by other compounds can be separated from each other. Phosphatidylcholine, phosphatidyl β-methylcholine and phosphatidyldimethylaminoethanol have R_F values of 0·33, 0·47 and 0·67, respectively. The lipid formed from TMAA has an R_F of 0·19. Furthermore, all these compounds can be clearly separated from each other after being mixed together. In addition to demonstrating that TMAA is incorporated into a lipid soluble derivative, this supports the observation of Bieber and Newburgh[13] that dimethylaminoethanol is incorporated into the phospholipid fraction and is not methylated to form phosphatidylcholine after incorporation.

MICROBIOLOGY

Recoveries of Bacteria after Drying *in vacuo* at a Bath Temperature of 100° C

FOR the purposes of preservation, micro-organisms may be dried either from frozen or liquid suspensions and the recoveries are governed by a number of factors, in particular by the nature of the suspending medium[1]. So far, bath temperatures of no higher than about 30° C appear to have been used to maintain suspensions in the liquid state during drying *in vacuo*.

Recent investigations of the resistance of bacteria to heat in the dried state[2,3] prompted an attempt to determine what fraction, if any, of bacteria would survive the actual drying process when it was carried out *in vacuo* and when the ampoules were held at a bath temperature of 100° C. Under these conditions, drying could be expected to proceed very rapidly.

Suspensions of the test organism, *Salmonella ndolo* (N.C.T.C. 8700), were prepared in 20 per cent sodium glutamate[2] and 0·1 ml. volumes of it were dispensed into ampoules (Edwards, 36/*H*/0800). The ampoules were connected to a horizontal manifold[4] charged with phosphorus pentoxide and the assembly was connected to a 'Speedivac *SSC*20' vacuum pump. Three drying treatments were studied; the pump was switched on (*A*) 5 sec before the ampoules were immersed in boiling water, (*B*) at the same time as the immersion, or (*C*) 5 sec after immersion. As the suspensions were subjected to reduced pressure and heat, vigorous spluttering occurred and the suspensions dried as foamy flakes on the walls of the ampoules. After 30 min, the bath was removed, the ampoules were constructed, replaced on the manifold and exposed for a further 30 min to 100° C at high vacuum, after which they were sealed *in vacuo*. The heat resistance of the sealed desiccates was tested by total immersion of the ampoules in a boiling water bath. Using "slow" rehydration procedures[3], viable counts on the desiccates were made immediately after the ampoules were sealed and at intervals during the secondary heating.

The only treatment of the three studied (Table 1) which resulted in heavy loss was treatment *C*, in which the ampoules were heated for 5 sec before evaporative cooling *in vacuo* began. With the other two treatments, where evaporative cooling began at the same time or 5 sec before the suspensions were exposed to high temperature, appreciable recoveries (5–16 per cent) of the organism were obtained. The recoveries from treatments *A* and *B* after heating the sealed ampoules at 100° C also indicate that they would yield desiccates with long storage life at ambient temperatures[3].

Table 1. RECOVERIES (LOG$_{10}$) OF *Salmonella ndelo* AFTER DRYING *in vacuo* AT A BATH TEMPERATURE OF 100° C AND AFTER FURTHER EXPOSURE OF THE SEALED DESICCATES TO 100° C

Drying treatment (see text)	Recoveries ($\log_{10}$) Immediately after ampoules were sealed	After exposure to 100° C for: 24 h	48 h
A	8·9 (16 per cent)	5·6	2·9
B	8·4 (5 per cent)	4·8	1·0
C	5·8	< 1	< 1

Number of organisms dried ($\log_{10}$) = 9·7.

No attempt has been made to measure temperature changes during the brief drying periods in these experiments. The cooling during drying *in vacuo* will be markedly modified by the heat input from the bath and the resulting temperatures could be expected to fluctuate violently.

Working at much lower temperatures, and in more slowly evaporating systems, other workers[1] found specimen temperatures within evacuated ampoules to be up to 60° C below the temperature of the bath surrounding the ampoules.

Whereas it is firmly established that glutamate protects organisms during heating in the dried state, there is no evidence from this or previous work that it does so during the early stages of drying. It is, of course, difficult to examine the two stages separately. No suggestion is made here that any of the treatments described should be seriously considered for preserving organisms, but the results do indicate that higher bath temperatures than have hitherto been contemplated could be used for drying some micro-organisms with a reasonable expectation of survival.

Fragile Cultures of *Escherichia coli* produced by Growth in High Concentrations of Various Salts

SUCROSE-DEPENDENT mutants have been reported which permit total isolation under mild conditions of cellular ribonucleic acid and proteins from actively growing cultures[1]. The considerable time and effort required to isolate equivalent mutants in strains of other genetic provenance had led us to search for a general method to

produce fragile growing cultures. This communication reports such a technique: growth in 0·5 M sodium sulphate or comparable concentrations of other salts.

Escherichia coli strain 3000 is cultivated at 37° C in a minimal medium composed (per l.) of potassium monohydrogen phosphate, 1·12 g; potassium dihydrogen phosphate, 0·48 g; ammonium sulphate, 0·5 g; $MgSO_4.7H_2O$, 0·49 g; $FeCl_3.5H_2O$, 0·5 mg; glucose, 2 g. The addition of increments of sodium sulphate to a series of flasks produces the altered growth curves shown in Fig. 1. At 0·5 M sodium sulphate (or 1 M potassium chloride or 0·5 M potassium sulphate), growth continues for several hours, then stops. During this period, cells become increasingly fragile up to a maximum of about 70 per cent of total fragility. Fragility has been measured by treating cells with 0·5 per cent sodium deoxycholate and measuring the decrease in the percentage of scattering at 420 mμ, the release of induced β-galactosidase, or the release of RNA, detected as [^{14}C]-uracil incorporated in acid-insoluble form (Fig. 2). The most sensitive index of the degree of total lysis is RNA release, as is also found with a sucrose-dependent mutant grown in fragile form[1].

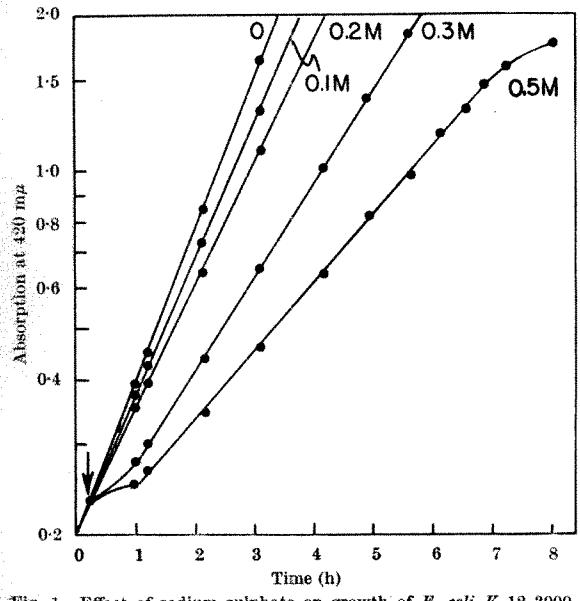

Fig. 1. Effect of sodium sulphate on growth of *E. coli K* 12 3000 in minimal medium at 37° C. At the point indicated by the arrow, the indicated levels of sodium sulphate were added to a series of cultures

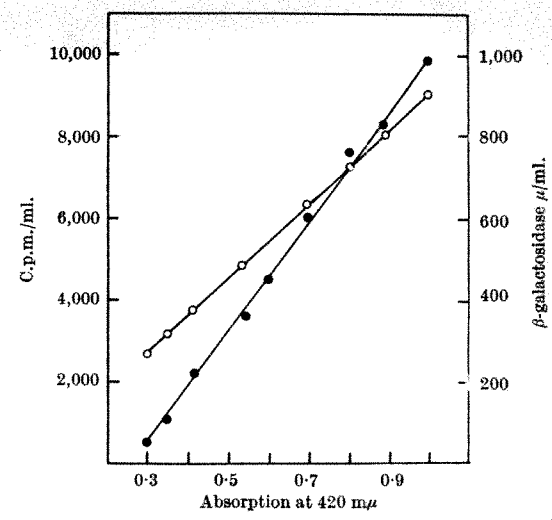

Fig. 3. β-galactosidase and RNA formation in fragile cultures. *E. coli K* 12 3000 was grown in minimal medium containing 0·5 M sodium sulphate and penicillin 15 U/ml., and 4 × 10^{-4} M IPTG. [^{14}C]-uracil (40 μg/ml., 20 μc./mg) was added at an optical density of 0·25. At intervals, samples were tested for β-galactosidase activity (— ○ —) and [^{14}C]-uracil incorporated into acid-insoluble RNA (— ● —). Each is formed in proportion to growth (measured as absorption of the culture at 420 mμ)

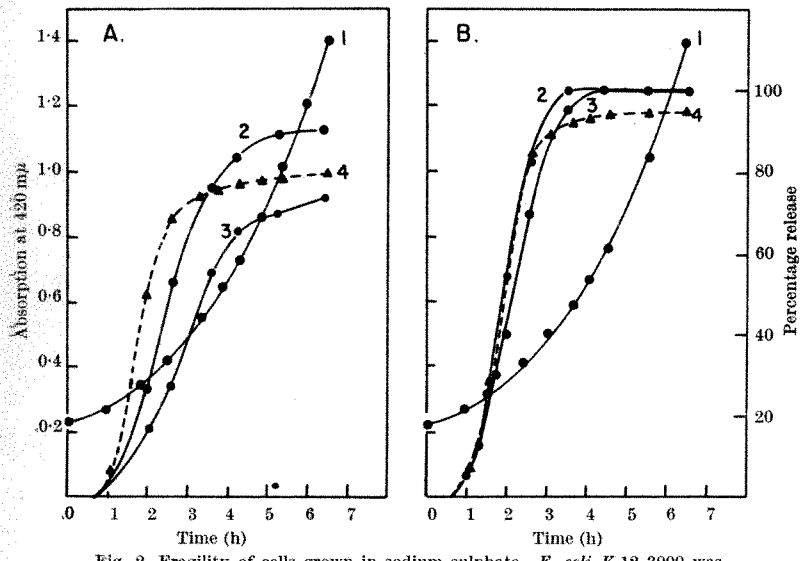

Fig. 2. Fragility of cells grown in sodium sulphate. *E. coli K* 12 3000 was grown in minimal medium containing 0·5 M sodium sulphate, 4 × 10^{-4} M isopropyl-β,D-thiogalactoside (IPTG) to induce the formation of β-galactosidase, [^{14}C]-uracil (0·02 μc./ml.), to label the RNA, and in presence of 15 U/ml. penicillin (*B*) or in its absence (*A*)
At intervals samples were centrifuged and cells were suspended in 0·5 per cent sodium deoxycholate in order to lyse them. The suspension was then tested for absorption at 420 mμ to see any reduction in scattering. Total β-galactosidase activity was also measured on toluenized cells with *o*-nitrophenol-β,D-galactoside as substrate (ref. 5). Total RNA was determined as [^{14}C]-uracil incorporated in acid-insoluble form. A portion of the same suspension was then centrifuged to remove unlysed cells and debris and the supernatant tested for β-galactosidase activity and RNA content to determine the percentage which had been released from the cells. Curve 1, absorption of the culture at 420 mμ; then, after lysis; curve 2, percentage of release of β-galactosidase activity; curve 3, percentage of release of [^{14}C]-labelled acid insoluble RNA; curve 4, percentage of decrease of optical density of cells at 420 mμ

Very similar results have been obtained with eleven *E. coli* strains and various media, although the optimum range of sodium sulphate concentration varies slightly in different cases. By contrast, *Bacillus megaterium KM* in comparable conditions goes through a fragile, spherical, non-growing stage (protoplast ?) and then lyses; the extent of the applicability of the technique to other types of bacteria is therefore not clear.

The degree of fragility can be increased to 100 per cent by the addition of 15 units per ml. of recrystallized penicillin *G* (1,500 U/mg)—a concentration which does not affect the growth of the cultures (Fig. 2) and has no detectable effect on cultures of the same strains growing in the absence of sodium sulphate.

While the synthesis of RNA or induced β-galactosidase in treated strains proceeds in proportion to growth (Fig. 3)—as does the formation of constitutive alkaline phosphatase, total protein and DNA (Fig. 4 and unpublished results)—the number of those forming colonies increases more and more slowly. The cause of this apparent discrepancy becomes obvious on observation with a microscope: high concentration of salt permits growth and the initiation of cell division, but the daughter cells sometimes remain attached in a pseudo-streptobacillar form.

Many chains break apart during handling, and all can be shaken apart (Table 1) without lysing more than 10–20 per cent

Table 1. FORMATION OF CHAINS OF VIABLE CELLS IN CULTURES GROWING IN 0·5 M SODIUM SULPHATE

Sample	Absorption at 420 mμ	Number of chains of $n = 1$ cells $n=1$	2	3	4	5	6	7	Total cells/ml. × 10^{-6}	Chains/ml. × 10^{-6}	Average No. cells/chain	Colony formers/ml. × 10^{-6}	Colony formers/cell
1	0·225	35	6						47	41	1·15	49	1·04
2	0·340	30	21						72	51	1·41	53	0·72
3	0·640	25	40	5		5			145	75	1·86	77	0·55
4	1·800	40	44	22	21	12			338	139	2·44	139	0·41
5	2·260	43	50	42	22	20	3	3	496	183	2·78	190	0·37
4*	–	217	49						315	266	1·18	310	0·98
5†	–	258	72						402	330	1·22	305	0·92

To a culture of *E. coli K* 12 3000 growing at 37° C in minimal medium, 0·5 M sodium sulphate was added at an absorption of 420 mμ of 0·210; cells continued to grow exponentially (see Fig. 1). At intervals, samples were diluted and fixed with 1 per cent formaldehyde, and total cells and number of chains containing n cells counted in a Petroff-Hausser bacterial counter. Duplicate samples were plated on rich medium to measure colony formers per ml.

* Sample 4 after 1 min agitation on a vibrator.

† Sample 5 after 1 min agitation on a vibrator.

of the cells. Nevertheless, progressively larger chains can be observed with time in carefully diluted samples; Table 1 indicates the appearance of chains noted in a typical experiment (that of Fig. 2). Because growth is rapidly arrested after two or three generations of fragile growth, it can be questioned whether the growth of treated cultures is ever truly "exponential". For many investigations, the distinction between slow exponential growth and linear growth is unimportant. Nevertheless, we have verified an exponential increase in total mass (Fig. 1.) and in the rate of uptake of [^{14}C]-leucine and [^{14}C]-uracil during growth of the cultures in sodium sulphate (unpublished results); in some experiments (Fig. 4) we have shown that, at any time during growth, induction of the internal enzyme β-galactosidase proceeds normally, producing an initial rate of enzyme synthesis which increases with growth as expected for a culture in the exponential phase. Likewise, the enzyme alkaline phosphatase, which is normally found at the cell surface[2], continues to be made, but is not released from cells; that is, very little leakage from or spontaneous lysis of these fragile cells occurs. We have confirmed the continued exponential synthesis of this "surface" enzyme, using the strain *S* 26 *C* 200 lacking alkaline phosphatase grown in sodium sulphate. This strain makes active enzyme constitutively in the presence of 5-fluorouracil[3]. Addition of 5-fluorouracil to fragile cultures at any time during growth therefore leads to the appearance of a burst of active enzyme, which is comparable in cultures growing in presence or absence of sodium sulphate (Fig. 4 compared with results of Rosen)[3].

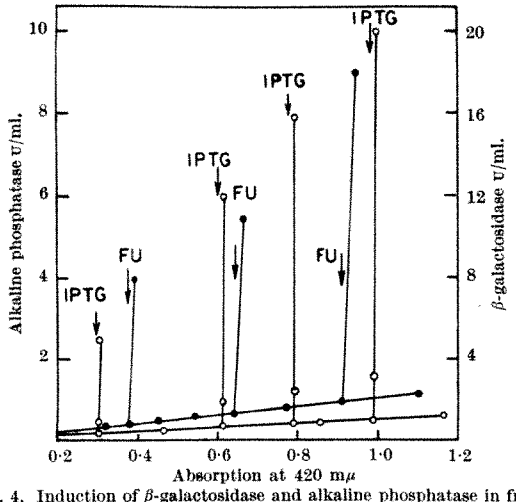

Fig. 4. Induction of β-galactosidase and alkaline phosphatase in fragile cultures. For β-galactosidase: *E. coli K* 12 3000 was grown at 37° C in minimal medium containing 0·5 M sodium sulphate and 15 U/ml. penicillin. At intervals, as indicated by the arrows, 4 ml. samples were transferred in 50 ml. flasks and 4 × 10^{-4} M IPTG was added. Immediately before the addition of IPTG and 2 min and 5 min afterwards, 1 ml. samples were chilled with frozen 20 per cent sucrose solution to stop further enzyme induction. Cells were centrifuged and resuspended in 0·5 ml. β-galactosidase activity was then determined on the toluenized cells (—○—). For alkaline phosphatase: *E. coli S* 26 *C* 200 was grown at 37° C in salts-glucose medium in presence of 0·5 M sodium sulphate and 15 U/ml. penicillin. At intervals, 3 ml. samples were transferred to 50 ml. flasks and incubated for 15 min in presence of 5-fluorouracil (2·5 μg/ml.) and thymidine (25 μg/ml.). Cultures were chilled in ice, and cells centrifuged and resuspended in 10 mM *tris*, *p*H 8·0. Alkaline phosphatase was then measured on toluenized cells using *p*-nitrophenylphosphate as substrate (ref. 6) (—●—)

In other studies we have noted that despite the sharp inhibition of *T*2 phage adsorption by high concentrations of salt, fragile cultures remain sensitive to infection by the phage, and are not sensitive to the action of actinomycin *D*. We conclude that a variety of processes (phage adsorption, resistance to actinomycin *D*, nearly complete cell division, etc.) which require a fairly intact cell envelope continue normally in cultures growing in fragile form in sodium sulphate. (In contrast, these processes are not carried out by penicillin or lysozymeversene "spheroplasts" with damaged walls[4].) Nevertheless, the fragile cultures grown in sodium sulphate can be totally lysed reproducibly, easily, and essentially instantaneously.

This investigation was supported in part by the U.S. Public Health Service. One of us (G. M.) is on leave from Istituto di Chimica Biologica, University of Genoa.

Inhibitory Effects of Other Antibiotics on Bacterial Morphologic Changes induced by Penicillin G

ALTHOUGH it has been suggested that tetracycline and chloramphenicol antagonize the antimicrobial activity of penicillin *in vitro* and *in vivo*[1–6], several investigators do not agree with these conclusions[7–9] and have suggested that variation in methods of assay and experimental conditions makes the interpretation of results very difficult. We carried out this work in order to investigate the problem using a different method from those used in previous experiments. Tests were, therefore, carried out to determine whether the addition of tetracyclines, chloramphenicol, and other antibiotics would prevent the formation of spheroplasts, a step which precedes the lysis of bacteria exposed to penicillin.

Three sets of paper disks containing antibiotics were prepared in the following manner: the disks, 7 mm in diameter, were cut from filter paper. One set was saturated with 0·3 ml. of a solution of penicillin *G* containing ten times the quantity of antibiotic that inhibited the growth of *Vibrio comma*. A second set was treated with a hundred times the minimal inhibitory concentration of the agents listed in Table 1. A third set of disks was prepared by first treating them with each of the drugs in Table 1. After drying, they were saturated with the same quantity of penicillin as was used in the first set. Heart infusion agar containing 5 per cent horse blood was inoculated by spreading 0·5 ml. of an 18-h broth culture of *V. comma* over the surface. After standing at room temperature for 1 h, the excess fluid was removed from the surface of the

Table 1. EFFECT OF VARIOUS ANTIBIOTICS ON MORPHOLOGICAL CHANGES IN *Vibrio comma* INDUCED BY PENICILLIN

Drugs inhibiting effect of penicillin	M.I.C.* for *V. comma*	Drugs producing no inhibition of penicillin	M.I.C.* for *V. comma*

* M.I.C., minimal inhibitory concentration (μg/ml.). M.I.C. of penicillin for *V. comma*, 35 units/ml.

agar and antibiotic disks applied. In the first experiment, the drugs were studied individually; in the second, combinations of them were used. The cultures were incubated at 37° C and cover slip impression preparations made at 2, 6 and 18 h. These were dried, fixed in absolute methyl alcohol, stained by the Giemsa method, and examined microscopically.

Long filaments and a few spheroplasts were seen in impression smears of agar cultures of *V. comma* exposed to penicillin alone for 2 h (Fig. 1). These changes rapidly progressed so that after 3 h of incubation two morphologically distinct layers, an inner one made up almost entirely of spheroplasts and an outer one consisting primarily of filamentous forms, developed at the border of the zone of growth inhibition. Increase in size of the spheroplasts was observed after 18 h (Fig. 2). When *V. comma* was exposed to 100 times the minimal inhibitory concentration of either chloramphenicol or tetracycline alone, the bacteria enlarged to several times their initial size but were not converted to filaments or spheroplasts (Figs. 3 and 4). The effects of other antimicrobial compounds (Table 1) on the morphology of *V. comma* grown in the presence of each compound individually were not studied; only the minimal quantity required to suppress growth of the organism was determined.

Spheroplasts and filamentous forms of *V. comma* did not appear when the organism was exposed to combinations of penicillin with tetracycline or penicillin with chloramphenicol; in the presence of the drug mixtures bacterial cell size increased to the same extent as was

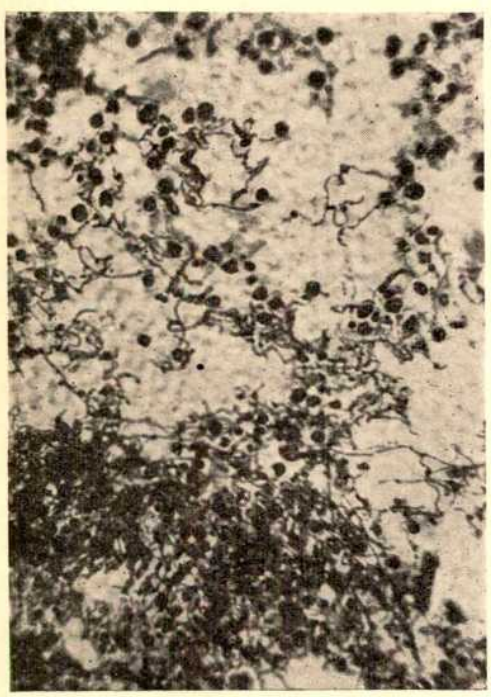

Fig. 1. *V. comma* after 2 h exposure to penicillin

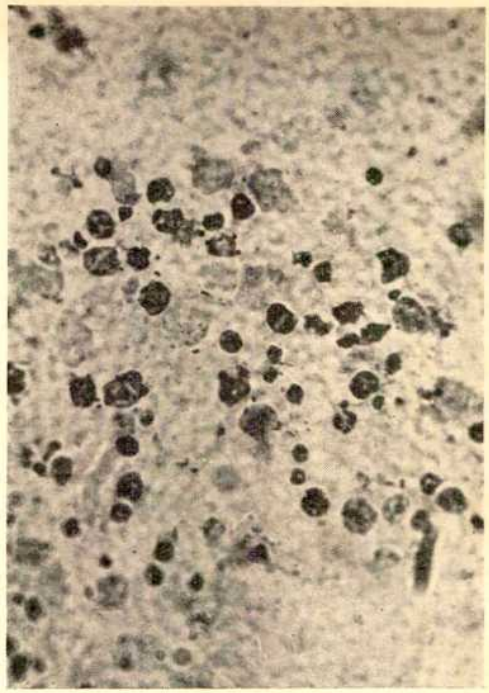

Fig. 2. *V. comma* after 18 h exposure to penicillin

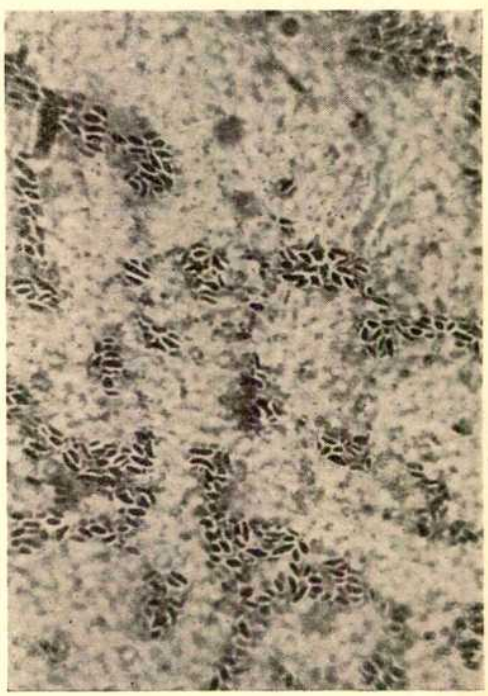

Fig. 3. *V. comma* after exposure to chloramphenicol or tetracycline alone and in combination with penicillin

observed when each of the "broad-spectrum" antibiotics was used alone (Fig. 3). Erythromycin, oleandomycin, kanamycin, neomycin, paromomycin, and streptomycin in combination with penicillin also completely inhibited the capacity of the latter to produce morphological changes. On the other hand, mixtures of bacitracin, *cyclo*serine, vancomycin, cephalothin, polymyxin, or colistin with penicillin induced morphological alterations in *V. comma* identical with those observed when penicillin alone was used.

The results of these investigations suggest that the bactericidal activity of penicillin *G* is suppressed by the

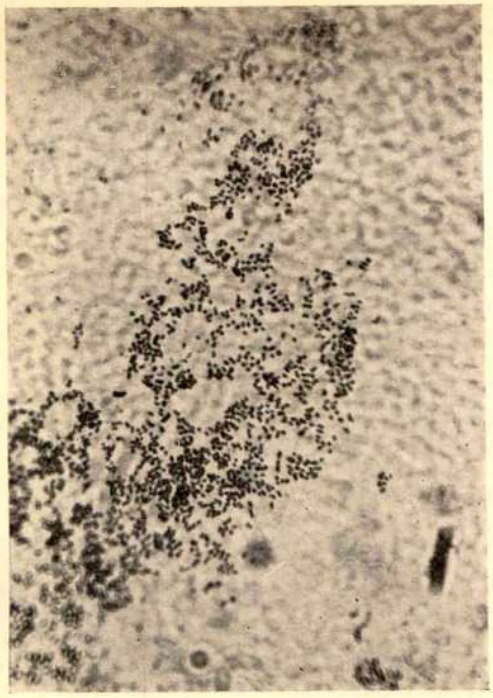

Fig. 4. *V. comma*, untreated

addition of certain classes of antibiotics but not by others. It appears that compounds which exert their antibacterial effects by interfering with protein synthesis suppress the induction of spheroplast and filament formation. Agents which act against organisms by interrupting the synthesis of the cell wall or by altering the cell membrane do not appear to interfere with the action of penicillin. These observations may cast some doubt on the efficacy of treatment of infected patients with combinations of tetracycline or chloramphenicol and penicillin—which are common forms of therapy. Furthermore, these findings may offer an explanation for the clinical failures that may result in cases where this type of antibiotic combination has been used to treat disease caused by penicillin-sensitive organisms. Removal of the "broad spectrum" agent has, in some cases, been found to result in prompt improvement and cure of the infection.

Level of Vitamin B_{12} in Propionate-grown *Prototheca zopfii*

THE colourless alga *Prototheca zopfii* does not require vitamin B_{12} as a growth factor, whereas at least half the marine algal flagellates and diatoms which have been investigated in pure culture[1], the protozoan flagellate *Ochromonas malhamensis*[2], and *Euglena gracilis*[3], have all been shown to have a growth requirement for this compound.

It has previously been shown that *Prototheca* assimilates propionate by a route involving β-hydroxypropionate and malonic semialdehyde[4,5]. This pathway is presumably independent of vitamin B_{12}, whereas the succinyl-Co*A* pathway of propionate metabolism, present for example in *Ochromonas*[6], requires a coenzyme form of the vitamin which functions in the isomerization of methyl malonyl-Co*A* to succinyl-Co*A*. Data on the level of vitamin B_{12} in extracts of *Prototheca* grown in medium rich in propionate were obtained as further evidence that the proposed pathway of propionate assimilation is the only mechanism involved in growth on this carbon source.

The organism was grown on propionate–mineral salts–thiamine medium as previously described[4], and the cell concentration at the time of collecting was determined by counting in a haemocytometer cell. The cells were collected quantitatively and resuspended at a final population of 10^8 cells/ml. in acetate buffer (*p*H 4·6) containing one drop of 1 per cent (v/v) potassium cyanide solution per 5 ml. of buffer. After autoclaving at 10 lb./in.^{2} for 10 min, the suspension was passed twice through a French press; it was then frozen and thawed, and autoclaved once more. Microscopic examination revealed that almost all the cells had been disrupted. The presence of cyanide stabilizes any vitamin B_{12} present; the extracts were protected from strong light.

Microbiological assays were carried out by Dr. M. E. Gregory of the National Institute for Research in Dairying, Shinfield, Reading. The assay using *Ochromonas* as a test organism failed to detect any vitamin B_{12} activity. The more sensitive *Lactobacillus leichmannii* assay revealed that the extract contained 0·08 mμg of vitamin B_{12}/ml., but the possibility arises with this organism that it is deoxyriboside activity which is measured rather than true vitamin B_{12}. *Euglena gracilis* was finally used as the test organism. The extract was centrifuged and the clear supernatant was used undiluted and diluted ten-fold. The undiluted extract gave no growth, and from this it can be concluded that cyanide or some other substance was present at an inhibitory level. In the case of the diluted extract it was found that growth increased with increasing addition to the assay cultures and the results calculated at two different levels were similar. The value obtained, 0·40 mμg/ml., can be regarded as a measure of true vitamin B_{12} activity.

Droop[1] has calculated that in an alga which requires vitamin B_{12} for metabolic processes the level will correspond to about three molecules of vitamin/μ^3; Hutner *et al.*[3] have reached a similar conclusion.

Assuming a molecular weight of 1,357 for the vitamin it can be shown that the level of the compound in *Prototheca* corresponds to only 200 molecules/cell. However, if Droop's calculations are applicable to any algal species, *Prototheca* (mean volume 1,440 μ^3) would contain about 4,300 molecules/cell and it is evident that the level of vitamin B_{12} in propionate-grown *Prototheca* is some twenty times lower than would be expected if the cells required the vitamin for their metabolism.

These investigations were carried out during the tenure of a Department of Scientific and Industrial Research research studentship.

IMMUNOLOGY

Lack of Natural Tolerance to Allotypic γ-Globulins in Rabbits

THE induction of immunological tolerance to soluble proteins can be achieved in rabbits by introducing a suitable dose into the foetus shortly before, or the infant shortly after, birth[1]. Yet in the case of the genetically determined IgG allotypes[2,3] in rabbits, neither tolerance nor sensitization has been recorded, although the maternal IgG, which comprises virtually all the plasma IgG of the offspring at birth, being received by way of imbibition of amniotic fluid[4] can contain an allotypic determinant not represented in the offspring's genotype[5-7] and against which the offspring can afterwards be immunized. The purpose of this communication is to document this lack of tolerance, although we cannot at present provide any explanation for it.

It might be mentioned that ostensibly the allotype situation should be well suited to the demonstration of tolerance, as the dose received by the infant is prenatal and relatively large, while the antigen (as judged by "normal" rather than adjuvant assisted immunization) is not strongly immunogenic (see later).

These results arose during the course of nearly a hundred routine immunizations of rabbits for the production of anti-allotypic sera; the fifty-two recorded were in animals of accurately known parentage.

The great majority of the rabbits were immunized by injection of *Proteus vulgaris* X19 coated with rabbit anti-*Proteus* antibody of the appropriate allotype[8]. In a few cases, antigen-antibody precipitates in complete Freund's adjuvant were used[2]. Both methods were satisfactory; the first was preferred partly as being very economical of antiserum IgG, partly to avoid the complications of antibody formation to antigens present in the complex (bovine seralbumin, ovalbumin, etc.), although, of course, antibacterial antibodies against *P. vulgaris* antigens regularly appeared. A single course of immunization consisted of five bi-weekly intravenous injections (in total 3×10^{10} organisms) coated with a maximum of 2 mg of anti-*Proteus* antibody. Two or three such courses with monthly rests between were sometimes necessary. The animals were bled one week after the last injection.

In all cases (about a hundred) such immunizations resulted in anti-allotypic antibody production, though sometimes three courses were necessary for satisfactory antisera.

In four cases, intravenous iso-immunizations of up to fifteen injections with normal rabbit IgG or whole serum were used without any evidence of antibody production; all these animals later produced antibody to the allotypic determinant originally used when immunized by the *P. vulgaris* method. The success of the *P. vulgaris* method may depend on an adjuvant effect excited by the endotoxin of the bacteria, combined with an advantageous cellular localization.

Of the six well-defined allotypic determinants those of the **b** locus were strongly immunogenic by this method, As4 being rather better than As5 and As6: the **a** locus determinants were more weakly so in the order As1 > As2 > As3. At least three courses were needed to raise a satisfactory anti-As2 or anti-As3. This gradient in immunogenicity is relevant in considering the tolerance situation.

Table 2. ANTI-ALLOTYPIC IMMUNIZATION IN WHICH MATERNALLY INDUCED TOLERANCE MIGHT HAVE OCCURRED

Rabbit No.	Mother's allotype	Offspring's allotype	Age at the time of first injection (in weeks)	Anti-allotypic antibody produced
1	As1,3/4,5	As3/4	12	anti-As1
2	As1,3/4	As3/4	13	
3	As1,2/4	As2/4	33	
4	As1,3/4,5	As3/4	45	
5	As2,3/4	As2/4	22	anti-As3
6	As2,3/4,5	As2,3/5	22	anti-As4
7	As1/4,6	As1/6	28	
8	As3/4,5	As3/5	90	
9	As3/4,5	As1,3/4	10	anti-As5
10	As1,3/5,6	As3/6	15	
11	As1/4,6	As1/4	15	anti-As6
12	As1/4,6	As1,3/4	40	

The results of the immunization of fifty-two rabbits of known parentage are given in Table 1. The figures in bold type indicate in twelve of these the presence of a maternal allotype which might have been expected to be tolerogenic. Table 2 gives further details of these twelve rabbits, in particular the age at which immunization started.

Results of other investigations[1,9] suggest that the duration of neonatally induced tolerance is dose-dependent. Recent results[9] indicate that the half-life of human IgG in the infant rabbit is 13 days: that of homologous IgG derived from the mother *in vitro* is not likely to be less than this. This figure is also consistent with the figures given elsewhere[10] in the homologous situation if allowance is made for increase of weight, and with earlier results[9] with rabbit IgG in infant rabbits during the first few weeks of life. If one can estimate the dose of maternal IgG received at birth, therefore, the amount of "antigens" remaining at any time thereafter, and available for the maintenance of tolerance, can be calculated.

The IgG content of the plasma of a newborn rabbit is at least one-third of the adult[10] (all being maternally derived), that is about 2 mg/ml. If the plasma volume is 5 ml. a birth dose of at least 10 mg is likely, especially as the animal's tissues and gut are saturated with the proteins of the amniotic fluid. Of this, only about half will be "tolerogenic" as in the nature of the experiment the mother must be heterozygous for the allotype concerned. The data[9] on human IgG, human and bovine seralbumin show that doses of between 2·5 mg and 0·1 mg received by the infants transplacentally were sufficient to establish tolerance which persisted in over two-thirds of cases, until the theoretical number of molecules of antigen remaining had fallen to a hundred or less. Moreover, when tolerance did break, after 6 months or more, the antibodies produced were of restricted specificity and usually non-precipitating. With a dose of 3 mg (about 10^{16} molecules) of heteroallotypic IgG in the situation under investigation, there would still be about 10^{11} molecules after 20 weeks and 10^5 after 40 weeks (as calculated from Table 2 in ref. 9). One would expect, therefore, that nearly all the immunizations recorded in our Table 2 would have been ineffective owing to tolerance, if the autologous antigen were of comparable efficiency with the heterologous.

Table 1. ANTI-ALLOTYPIC IMMUNIZATION OF RABBITS OF KNOWN PARENTAGE

								1	As2,3/4		
								1	As1,3/4,6		
Total	7		11		9		9		10		6

In all cases satisfactory anti-allotypic antisera were produced. Those in bold type indicate the twelve cases where the immunization was against an allotypic determinant present in the mother.

In all the anti-allotypic immunizations recorded there was nothing to choose, so far as the strength and reactivity of the sera went, between those in which some measure of tolerance might have been expected owing to maternal transfer, and those which it would not. It is possible that the endotoxin contained in *Proteus vulgaris X*19 might act to break tolerance when this method of immunization is used; but if tolerance had ever been established one would still expect some suppressive effect with immunizations started at 10–15 weeks. Because isologous IgG is so poorly antigenic by non-adjuvant-assisted immunization even in an animal where tolerance could not have been induced maternally, it is difficult to decide whether in fact it is possible for any degree of tolerance whatever to be induced "naturally" by placental transfer. Experiments to throw light on this situation are in progress.

Cellular Localization of Carbon-14 Endotoxin in Cultured Leucocytes

IT is well known that the administration of endotoxin results in a very rapid increase in size of the reticulo-endothelial system (RES)[1]. The RES is enhanced not only quantitatively but also qualitatively, in that radioactively labelled endotoxin is more rapidly removed by the RES of animals which have previously received endotoxin[2]. Tritiated endotoxin administered subcutaneously is found initially in the intraendothelial cells of the lymphoid channel, and the sinusoidal cells of the draining lymph node. By 24 h the large mononuclear cells, infiltrating the area, contain the labelled material[3]. In a similar fashion, labelled antigens (such as non-endotoxin) which are administered subcutaneously localize in the macrophages of the medullary sinuses and the lymphoid follicles of the draining lymph nodes[4]. They are also more rapidly and avidly taken up by immune and immunologically tolerant animals[5].

It has been reported that labelled endotoxin is found mainly in the buffy coat platelets, only 4–8 per cent of the granulocytes, even fewer monocytes, and not at all in small lymphocytes or the red blood cells[6,7]. A recent report from this laboratory demonstrated that endotoxins stimulate lymphocyte proliferation *in vitro* and that these effects were related to the antigenicity of the endotoxins used[8]. In the present investigations, labelled endotoxin was found in the macrophages of leucocyte cultures which manifested concomitant lymphocyte proliferation.

The peripheral leucocytes from four healthy young adult human beings were obtained and prepared by methods previously described[8]. Their cell suspensions in tissue culture medium were divided into 12 ml. portions. To the first portion 0·5 ml. of isotonic saline was added, to the second 2 μg/ml. *Salmonella enteritidis* endotoxin, and to the third portion 2 μg/ml. of the same *S. enteritidis* endotoxin biosynthetically labelled with carbon-14 (specific activity 11·2 mc./mg, both kindly supplied by Dr. Edgar Ribi). The cell suspensions were then left undisturbed for 5 days at 37° C.

Four hours before collection, polystyrene particles (0·2 ml., 1 : 100 saline dilution, 1·3μ diameter, Dow Chemical Co., Midland, Michigan) and 0·33 μg/ml. 'Colcemid' (CIBA Pharmaceutical Co., Summit, N.J.) were added to each culture. The particles are often phagocytized by macrophages, thus aiding in their differentiation from non-phagocytic transformed lymphocytes[9]. 'Colcemid' arrests mitosis and therefore elevates the mitotic index to measurable levels[10]. The cell suspensions were collected, fixed with absolute methyl alcohol and glacial acetic acid (9 : 1), and slides prepared and analysed as previously described[8].

Tritiated thymidine (^{3}HTdr 0·360 c./mmole specific activity, Schwarz Bioresearch, Inc., Orangeburg, New York) was added, 4 h before collection, to those cultures which did not contain carbon-14 endotoxin from two of the subjects. Autoradiographs using 'Kodak *AR*10' were prepared and developed after 2, 6 and 20 weeks of exposure[11].

S. enteritidis endotoxin with and without carbon-14 label evoked a significant increase in the median proportion of transformed lymphocytes from 0·5 per cent in the unstimulated cultures to 10·5 and 6·0 per cent, respectively (Table 1). Concomitantly, the median mitotic index increased from zero in the unstimulated to 12/1,000 mononuclear cells in the carbon-14 endotoxin-treated cultures. Corroborating evidence of lymphocyte proliferation in response to *S. enteritidis* endotoxin was evident from the increased proportions of ^{3}HTdr labelled mononuclear cells present in the cultures. The proportion of macrophages in the unstimulated cultures was similar to the proportion in those exposed to labelled and unlabelled endotoxin. These findings indicate that both endotoxins stimulated lymphocyte transformation equally well and that the radioactive isotope did not cause sufficient cell injury to inhibit this response.

Table 1. EFFECTS OF CULTURING LEUCOCYTES FOR 5 DAYS WITH *S. enteritidis* AND CARBON-14 *S. enteritidis* ENDOTOXIN

Additive	Cell differential	Subjects A.B.	K.S.	S.P.	N.B.	Median response
Saline	Mitotic index	1	0	0	0	0
	Macrophages (%)	12	40	23	20	21·5
	Transformed lymphocytes (%)	2	1	0	0	0·5
	Mononuclear cells labelled with ^{3}HTdr (%)	—	—	0	0	0
S. enteritidis	Mitotic index	0	4	0	0	0
	Macrophages (%)	13	15	57	13	13
	Transformed lymphocytes (%)	8	4	10	4	6
	Mononuclear cells labelled with ^{3}HTdr (%)	—	—	3	3	3
Carbon-14 *S. enteritidis*	Mitotic index	0	10	16	14	12
	Macrophages (%)	33	26	30	3	14·5
	Transformed lymphocytes (%)	3	5	16	21	10·5
	Transformed lymphocytes labelled with carbon-14 *S. enteritidis* (%)	0	0	0	0	0

The autoradiographs of the carbon-14 endotoxin-stimulated cultures did not reveal any localization of label greater than that of the background over any of the small or transformed lymphocytes in any of the four subjects (Fig. 1). Unfortunately, both the platelets and red blood cells are destroyed by the method of fixation used, so that their degree of labelling could not be assessed. In the two experiments in which the friable macrophage cytoplasm was least disrupted by the method of fixation, the carbon-14 label was markedly concentrated over or near the macrophages (Fig. 2). The grain counts and the proportion of macrophages labelled could not be determined because the labelling was too heavy and the carbon-14 scatter too great.

Thus, the carbon-14 label of the *S. enteritidis* endotoxin was taken up *in vitro* only by the macrophages, and not noticeably by the lymphocytes which were stimulated to transform. This is similar to the observations of lymphocyte transformation with *Mycobacterium battei*

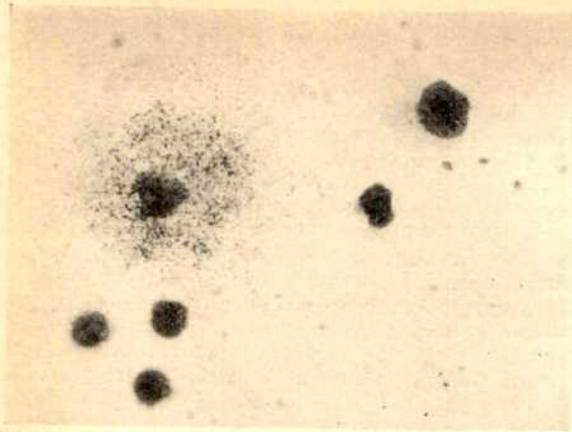

Fig. 1. Macrophage showing localization of carbon-14 endotoxin label in the region of its cytoplasm. Note the unlabelled transformed lymphocyte in the right corner of the picture, and unlabelled small lymphocytes below the macrophage (magnification × *c.* 410)

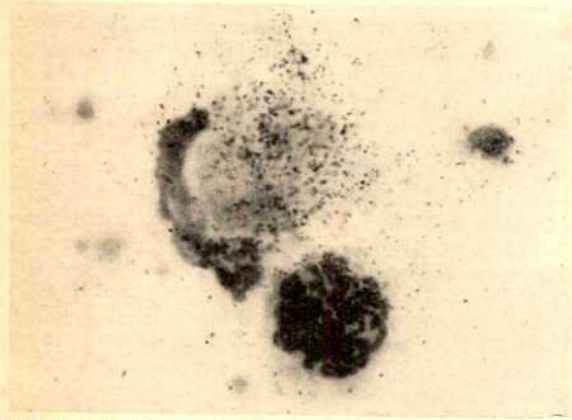

Fig. 2. A macrophage manifesting localization of carbon-14 endotoxin label flanked by an unlabelled early prophase mitotic figure (magnification × *c.* 410)

organisms. Most of these organisms are phagocytized by macrophages, and none is detectable within the transformed lymphocytes[12]. Furthermore, lymphocytes purified in nylon or glass bead columns fail to transform *in vitro* with antigens, despite the fact that these antigens are successful in transforming lymphocytes in cultures of the same leucocytes before separation[13]. These findings suggest that macrophages may play an intermediate part in the secondary *in vitro* lymphocyte transformation response to antigens.

HAEMATOLOGY

N Blood Group System of Pigs

THE N blood group system of pigs has been identified by Hála and Hojný[1] by means of an antiserum called anti-Na. The corresponding antigen, Na, was considered to be the product of a gene, N^a. They describe a system of two alleles, N^a and $N^{(a)}$—the latter symbol denotes the absence of N^a. Two additional factors of the N system, Nb and Nc, defined by the antisera anti-Nb and anti-Nc, have been identified in this laboratory. Inheritance studies show that there are three genes: N^a, producing factor Na, N^b, producing factor Nb, and N^{bc}, producing factors Nb and Nc. N^a and N^b are a pair of contrasting alleles, forming a closed system; Nc is a sub-group of Nb, and has not been found in its absence. It was not possible to verify Hála and Hojný's claim that Na is a soluble antigenic substance.

Large-scale Crystallization of Purified Human Foetal Oxyhaemoglobin from Cord Blood

THE crystal shape of pure human adult haemoglobin (HbA) has unanimously been described as that of well-developed, symmetrical bipyramids[1,2]. Investigations of the crystal forms of human foetal haemoglobin (HbF), however, have revealed divergent results: hexagonal rhombic plates[3], probably monoclinic forms[4] and a mixture of dodecahedra and square prisms[5] have been reported. All these investigations were carried out on cord blood. Our methods allow the investigation of pure crystalline foetal haemoglobin.

Red cells from fresh heparinized cord blood of full-term and premature infants were washed five times with 0·9 per cent sodium chloride solution and haemolysed by the addition of 1·4 parts of twice distilled water to 1 part erythrocytes. All preparations were carried out at a temperature of 4° C to exclude an increase in methaemoglobin concentration. The relative proportion of HbF was estimated as described by Betke[6]; haemoglobin and methaemoglobin were repeatedly determined as cyanmethaemoglobin. Alkali denaturation of HbA was carried out according to Chernoff[7]. 100 ml. of an approximately 15 per cent haemoglobin solution were denaturated by the addition of 800 ml. 1/12 N potassium hydroxide for 2 min to destroy HbA completely. The reaction was interrupted by the addition of a 450 ml. saturated solution of ammonium sulphate containing 0·95 ml. concentrated hydrochloric acid per 100 ml. of the salt solution. The reaction mixture was adjusted to *p*H 7·0. After centrifugation (4,000*g* for 30 min) and after decanting carefully the deep red and clear supernatant, denaturated HbA, stromata and the more insoluble proteins in the sediment were discarded. 100 ml. of 0·5 M phosphate buffer, *p*H 7·35, were added to 1 l. supernatant. The salt saturation was brought up to 75–80 per cent by gradual addition with thorough stirring of solid ammonium sulphate, while the *p*H was maintained at at least 6·5 (if necessary more phosphate buffer (*p*H 7·35) was added). The solution was then centrifuged again (4,000*g* for 30 min) and a deep red sediment containing the foetal haemoglobin appeared at the bottom. HbF was then dissolved in 0·25 M phosphate buffer (*p*H 7·4), placed in dialysis bags and dialysed

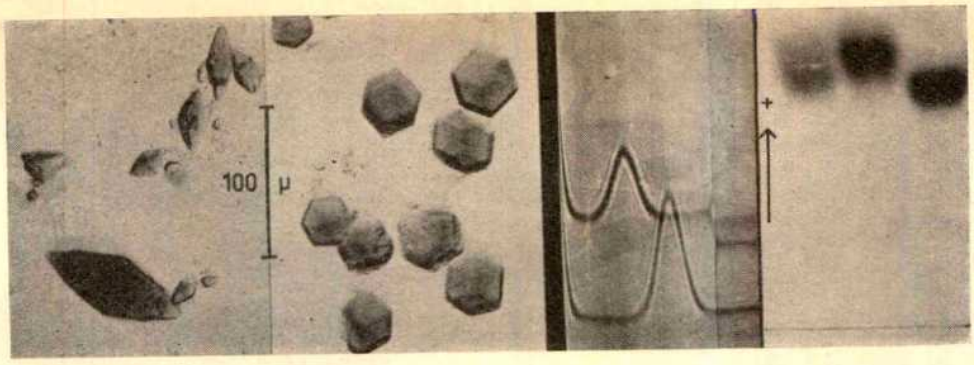

Fig. 1. *a*, HbA crystals. *b*, HbF crystals. *c*, Ultracentrifugation: 44 min, 42,040 r.p.m., 0·8 and 0·4 g per cent HbF in 0·02 M phosphate buffer, *p*H 7·4. *d*, Starch-gel electrophoresis: lithium buffer, *p*H 8·04, (120 V, approximately 12 mamp, 14 h). Left to right: cord blood, HbA, crystalline HbF (all samples at a concentration of 250 mg per cent haemoglobin)

against the same buffer to remove ammonium sulphate. The contents of the bags were centrifuged (40,000*g* for 20 min) and the supernatant HbF solution crystallized by dialysis against 2·8 M phosphate buffer of *p*H 6·8 using the method of Drabkin[2]. During these procedures, 8–12 per cent methaemoglobin developed. The addition of stoichiometric amounts of sodium thiosulphate to the dialysis fluid results in the reduction of this methaemoglobin to haemoglobin. After continued dialysis for about 12–18 h the first crystals could be identified by microscopic examination. The buffer was then renewed to allow larger growth of crystals and dialysis continued for several days to several weeks. 70–80 per cent of the original foetal haemoglobin specimen could be crystallized.

From solutions of pure foetal haemoglobin our procedure yielded exclusively isomorphous crystals, that is, dodecahedra, whereas crystals from human adult haemoglobin are typical orthorhombic bipyramids (Fig. 1*a*, 1*b*).

The completeness and uniformity of the crystallized foetal haemoglobin were examined (following separation of HbF crystals from the mother liquor by rapid filtration with suction on a Buchner funnel) as follows:

(1) *Spectroscopic examination* of dissolved HbF crystals showed the conventional plots of the haemoglobin absorption spectra, and the tryptophan fine structure band typical of HbF[8] at a wave-length between 288–289 mμ.

(2) *Ultracentrifugation* (Spinco 'Model *E*' analytical ultracentrifuge) revealed a sedimentation constant in Svedberg units (S_{20}) of 4·4 and a diffusion constant (D_{20}) of 6·6 (values extrapolated to zero concentration). The molecular weight calculated from S_{20} and D_{20} was 66,000. This figure agrees with those reported for foetal haemoglobin[9] (Fig. 1*c*).

(3) *Starch-gel electrophoresis*[10] of re-dissolved pure crystalline HbF and HbF in cord blood haemolysates showed a comparable electrophoretic mobility (Fig. 1*d*) equally with lithium buffer, *p*H 8·04, and *tris*-citrate buffer, *p*H 8·7 (ref. 11).

Measurements with the petrographic polarization microscope of crystals of pure human foetal haemoglobin showed invariably and uniformly isomorphous cubic forms (dodecahedra) so far as definite conclusions can be reached with optical investigations. Dodecahedra have been found in crystallized cord blood preparations (carbonmonoxyhaemoglobin) together with square prisms by Zinsser and Tang[5] using X-ray crystallographic measurements.

We thank Prof. H. Roemer and Prof. K. Knörr for supplying cord blood and Dr. D. Stöffler for crystallographic investigations. We also thank Mr. U. Rudolph for the measurements with the ultracentrifuge and Prof. H. Haselmann for the photographs of the crystals.

HISTOCHEMISTRY

Staining of Paneth Cells with Thioflavine *T*

Since the thioflavine *T* (T.T.) fluorochrome method[1] was first recommended for the demonstration of amyloid its use has been extended widely. Uptake of the dye has been shown to occur with myeloma casts[2], muciphages in the intestinal mucosa[3,4], keratin[4], mast cells[5,6], myelin figures in neurones of infantile amaurotic idiocy and some of the component cells in the granular cell myoblastoma[7], acidophils in the pituitary[8], juxtaglomerular apparatus cell granules in the kidney[6,9] and zymogen granules in the pancreas of mice[6].

While investigating further possible uses of this fluorochrome it was discovered that Paneth cells in the human jejunum were also strongly positive. As a stage in the usual method, haematoxylin is ordinarily used as a non-specific quencher of tissue autofluorescence. It became apparent, however, that the uptake of T.T. by Paneth cells was largely dependent on a more specific action of haematoxylin.

In hydrated paraffin sections of formalin-fixed jejunal mucosa obtained by peroral biopsy it was possible to compare in the same section the strongly autofluorescent argentaffin cell, the muciphage and the Paneth cell. The usual staining procedure[1] with slight modification is as follows: (i) haematoxylin 5 min; (ii) two rinses in distilled water; (iii) T.T. for 5 min; (iv) rinse in 1 per cent glacial acetic acid then place in same for 3–5 min;

(v) two rinses in distilled water followed by mounting in equal parts of glycerin and distilled water. We used the haematoxylin of Krutsay[10] which is constituted as follows: 0·5 per cent haematoxylin, 5·0 per cent potassium alum, 0·02 per cent potassium iodate, 0·5 per cent hydrochloric acid and distilled water. This acid haematoxylin gave better results than those of Ehrlich, Mayer, Weigert and an alcoholic Krutsay solution. The T.T. was prepared according to Janigan[9]. Table 1 shows the results of omission and simple sequence variation of certain stages in the staining procedure. It is clear that the haematoxylin effectively potentiates the T.T. fluorescence of Paneth cells while quenching the autofluorescence of the background, nuclei and argentaffin cells.

In order to elucidate this phenomenon, two further series of sections were treated as in the standard method except that, in turn, the haematoxylin solution minus hydrochloric acid, and then each of the constituents of the solution, alone and in combination, were substituted for the full haematoxylin in the staining procedure. In one series they were mounted and examined for fluorescence after this stage—the T.T. stage was omitted. The results are shown in Table 2. Except for hydrochloric acid and haematoxylin itself, none of the other isolated constituents of the stain or combinations of them appears to play a part in the potentiation of the fluorescence of Paneth cells. A simple aqueous solution of haematoxylin gave the same results as the non-acid containing solution and thus the presence of potassium alum and potassium iodate is without effect. Haematoxylin is not acting simply as a quencher of background and non-specific fluorescence as the actual intensity of fluorescence of the Paneth cell is markedly enhanced by its use. While haematoxylin alone and hydrochloric acid alone seem to be effective, neither when used alone is as effective as the combined acid haematoxylin solution.

Table 1

	Auto-fluorescence*	Krutsay†	Krutsay-T.T.	T.T.	T.T.-Krutsay

,, ,, + T.T.	+ + lg	±	±
Aqueous haematoxylin	+ bw	−ve	+ oy
,, ,, + T.T.	+ + lg	+ + oy	− ve

It will also be noted from Table 1 that, as observed by other workers, muciphages are fluorescent after the usual staining procedure. With the filter system we used, however, a colour quite distinct from Paneth cells is produced. Moreover, if T.T. is applied before the haematoxylin the fluorescence of muciphages virtually disappears (compare Figs. 1 and 2). Why the reversal of the staining sequence has this effect is not understood, but because the Paneth cell fluorescence remains unchanged it is obvious that it has a greater affinity for T.T. That this might arise from metallic zinc, known to be present within Paneth cells, was not substantiated. Sections were stained before and after extraction of zinc by the method of Studzinski[11] without any effect on the result. As a control procedure,

Fig. 1. High-power photomicrograph of jejunum stained with the Krutsay haematoxylin-T.T. sequence. Note the strong fluorescence of both the Paneth cell granules and the cytoplasm of the muciphage. (× 1,500)

Fig. 2. Parallel section to that of Fig. 1, which demonstrates the effect of reversing the staining procedure. The Paneth cell granules fluoresce brightly while the fluorescence of the muciphage cytoplasm is scarcely apparent. (× 1,500)

sections of gastric mucosa and prostate were also treated similarly (zinc is also present in the gastric parietal cell and in prostatic epithelium). While both these cell types were not stained by T.T., the acid-producing gastric oxyntic cell showed an uptake comparable with that of the Paneth cell. This was regarded as additional con-

firmation of the importance of an acid moiety in the staining reaction.

CYTOLOGY

Fine Structure of Experimentally Produced Subsynovial Carbon Granuloma

RECENT electron microscopic investigations of synovial joints have been concerned with the phagocytic nature of synovial membrane cells[1,2]. In order to investigate this phenomenon further, 1 c.c. of colloidal carbon in the form of Indian ink (particles 200–2000 Å in diameter) was injected into the knee joints of rabbits. 104 days later the animals were killed, and large granulomata were evident in the subsynovial tissues. This report is concerned with the structure of these carbon granulomata.

Portions of synovial membrane and subsynovial tissue were fixed in 4 per cent glutaraldehyde[3] or in Millonig's[4] fixative and embedded in 'Epon'. Thick sections (1·5μ) were prepared for investigation under the light microscope and stained with 0·5 per cent aqueous safranin. Ultrathin sections were also cut and mounted on carbon-coated grids and stained with uranyl acetate[5] and lead citrate[6]; these were investigated with an RCA *EMU*-2 electron microscope. An estimation was made of the character and relative number of subsynovial inflammatory cells present per high-power light microscopic field for each experimental stage. These cells fell into three groups: polymorphonuclear leucocytes, cells of the macrophage series (histiocytes, macrophages and primitive cells) and unclassified cells. By combining the light and electron microscopic observations, the phagocytic contributions of the synovial membrane and that of the invading inflammatory cells could be distinguished.

The cell most involved in the removal of particulate matter of this size from the joint cavity is the invading macrophage. A progressive infiltration of the macrophages could be seen: these were first observed free of carbon in the subsynovial tissues, then seen to penetrate the synovial membrane, to enter the joint cavity and finally to appear once more in the subsynovial tissues but with an abundance of colloidal carbon in their cytoplasm. Such cells appeared to migrate toward one another so that light microscopic examinations carried out 104 days after injection revealed the large carbon granulomata beneath the synovial membrane (Fig. 1). Under the light microscope, the areas where the cells congregated could be seen to be surrounded by a collagenous capsule which possessed a profuse blood supply. The cytoplasm seemed to be totally saturated with carbon particles. The nuclei contrasted sharply and often showed a prominent nucleolus.

Under the electron microscope, the configurations of the plasma membranes of adjacent macrophages varied from the more numerous long, thin finger-like processes 600–1200 Å in length to the less numerous bulb or club-shaped terminations (Fig. 2). Occasionally, when observed in cross-section, these processes exhibited a circular

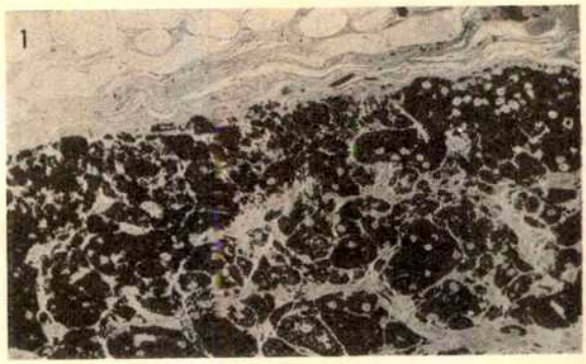

Fig. 1. Light micrograph of subsynovial tissue fixed 104 days after intra-articular carbon injection. The area of the granuloma is surrounded by fibrous tissue. The nuclei, many of which show a prominent nucleolus, contrast sharply with the carbon filled cytoplasm. Stained with aqueous safranin. (× 1260)

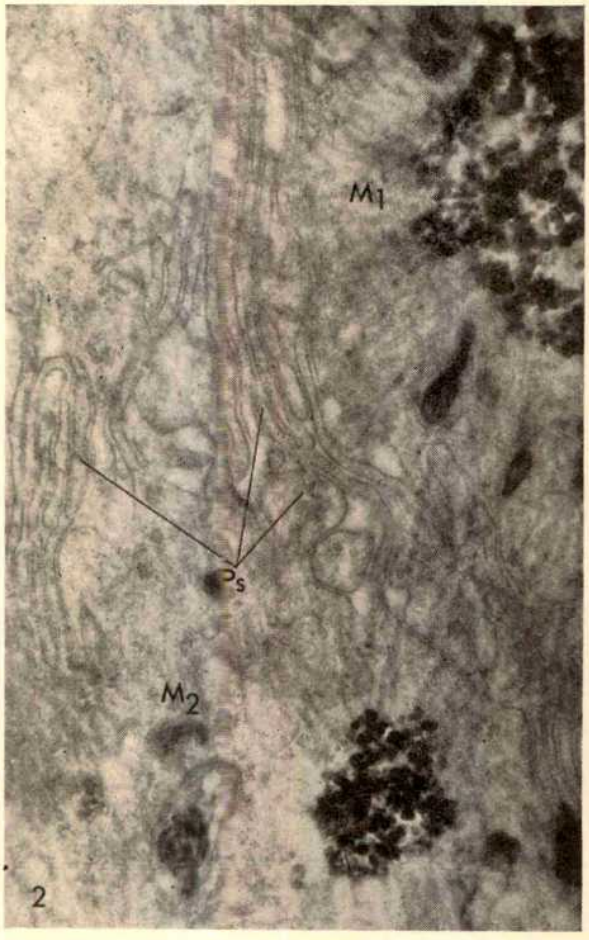

Fig. 2. Electron micrograph of adjacent macrophage-like cells (M_1 and M_2) fixed 104 days after intra-articular carbon injection. The extensive interdigitation (*Ps*) of plasma membranes by adjacent cells is well demonstrated. (× *c.* 27,700)

profile; however, an elongated profile was more usual, which indicated that most processes are probably flattened and leaf-like and vary greatly in width but are uniform in thickness.

Although extensions of plasma membrane of adjacent cells closely approached each other, direct contact between adjacent granulomatous cells was not observed. A space of 20–40 Å (Fig. 2) separated adjacent cells so that a direct cell to cell contact was not observed. A similar behaviour has been observed[7] in tissue culture and termed "contact inhibition". These plasma infoldings were carefully examined for evidence of thickenings of the plasma

membrane, condensation of submembranous cytoplasm and increased density between two cell membranes characteristic of desmosomes of adhesion plates found in epithelia[8] and in the nervous system[9]. None of these features was observed.

When the phagocytic cells involved in the formation of granulomata become closely bound together, cytoplasmic inclusions other than carbon particles for the most disappear; this is especially so in the central portion of the cytoplasm and around the nucleus. Moreover, in larger granulomata, the cells lying in the centre of a granuloma show few organelles either centrally or peripherally. A similar distribution of organelles has been noted in the giant cells of the lung[10]. Several explanations can be offered; for example, that the fixatives are not able easily to penetrate these large cytoplasmic masses. However, the two different fixation procedures used in the present work give comparable results, which indicates that the method of tissue preparation is not involved. Another possibility is that the more peripherally located cells have been added to the granuloma more recently than the centrally located cells. A fully developed granuloma as seen at 104 days post-injection is apparently neither mobile nor engaged in the production of extracellular substances (that is, proteinaceous fibres). It seems probable, therefore, that these cells would not possess as many cytoplasmic organelles as are observed in cells engaged in more active functions.

This investigation supports the previous findings[10] that giant cells are not formed, as had been suggested earlier[11,12], as a result of the presence of individual particles too large to be phagocytosed by single cells.

Ultrastructural Transport Mechanism of Messenger Ribonucleic Acid in the Young Oocytes of Amphibians

IT is now generally accepted that the nucleus is an active centre of ribonucleic acid (RNA) synthesis and is perhaps the sole source of cellular RNA (ref. 1). Much evidence has accumulated to substantiate this view, which has raised the interesting question of the possible role of RNA as a carrier (messenger) of gene specificity to the cytoplasm, where the ribosomal RNA is thought to be involved directly in protein synthesis.

The passage of nuclear RNA into the cytoplasm has recently been observed by Balinsky and Devis[2] and Beermann[3] in the course of electron microscope studies of growing oocytes of *Xenopus laevis* and of the salivary gland cells of *Chironomus tentans*. No previous account has been given of the way in which such a passage occurs, except for the description by Beermann, in which he says that the round particles of about 300 Å in diameter possibly transport forms of the messenger, arrive at the nuclear envelope, get caught in the pore and penetrate it, and change their shape into a rod or a thread. The present communication is concerned with the ultrastructural transport mechanism of the messenger in the young oocytes of amphibians.

Small pieces of the ovaries of *Triturus pyrrhogaster* and of *Rana nigromaculata* were transferred immediately to cold 1 per cent osmium tetroxide buffered with veronal acetate. After fixation, the fragments were divided into single oocytes or small groups of oocytes. They were embedded in 'Epon 812' epoxy resin. Young oocytes ranging from 100μ to 300μ in diameter were sectioned with the Porter–Blum microtome, and thin sections were stained with uranyl acetate. They were examined with the Hitachi '*HU-11A*' electron microscope.

Electron micrographs of the young oocytes of both species reveal that the nucleoplasm is irregularly distributed, with many coarse granulated patches. These patches consist of electron-dense particles about 300 Å in diameter and fibrous structures of the lateral loop of the lampbrush chromosome conveying the particles. These particles are thought to be the result of gene activity on the lateral loop, and they may be transport forms of the messenger. Sometimes the granulated loops are observed facing the nuclear pores. In such a region, flakes of electron-dense matter can often be found in the cytoplasm, suggesting outflow of the material through the nuclear pores (Figs. 1 and 2). Indeed, high magnification of such a region clearly shows that the round particles detached from the lateral loop penetrate the pores, leaving behind their conveyor as a smooth loop (Fig. 2). On the other hand, in the cytoplasm near the nuclear pore, expelled material can be seen taking the shape of spindles or dumb-bells. It remains in this form for a time until it diffuses into the perinuclear cytoplasm. It is also found that the electron-dense flake consists of very fine filamentous structures running parallel to its long axis. It is tempting to assume that the messenger molecule, so long as it is within the nucleus, remains attached to the lateral loop, but it detaches from the loop (conveyor) when it is just ready to pass the pore. This may happen under the influence of certain preferential factors from the cytoplasm, because the granulated loops do not necessarily show this behaviour even if they lie near the nuclear pore. These particles cannot occur floating freely from the loops in the nuclear sap as is the case with the salivary gland nucleus of *Chironomus*[3]. According to Beermann, two large Balbiani rings in the salivary gland nucleus of this species produce characteristic round particles of about 300 Å in diameter. These are probably ribonucleoprotein as they are sensitive to RNase and trypsin. These particles are found floating in the nuclear sap, and, under certain conditions, they pass through the pores and change their shape into a rod or a thread. After having passed, however, they seem to disappear in the cytoplasm. He assumes that the messenger molecules are combined with transport protein, but that when they have passed through the nuclear pore they leave their vehicle protein behind in order to be picked up by ribosomes, while the vehicles themselves return to the nucleus. Balbiani rings and lampbrush chromosome loops are similar to each other in that both have a high RNA/DNA quotient and are characteristic round particles of similar dimensions. In addition, the matrix surrounding both the Balbiani rings and the lateral loops consists of RNA and protein. It is considered that two substances are actively synthesized at the activated chromosomal strands, and some quantity of RNA eventually becomes transferred to the cytoplasm. Although the mechanism of such a transfer may be different in detail, depending on the species of animals and even in different kinds of cells, it seems likely that it is fundamentally similar in all animals. At the present time it is not clear whether the differences between insects and amphibians in the time of detachment of the particles from the conveyor are due

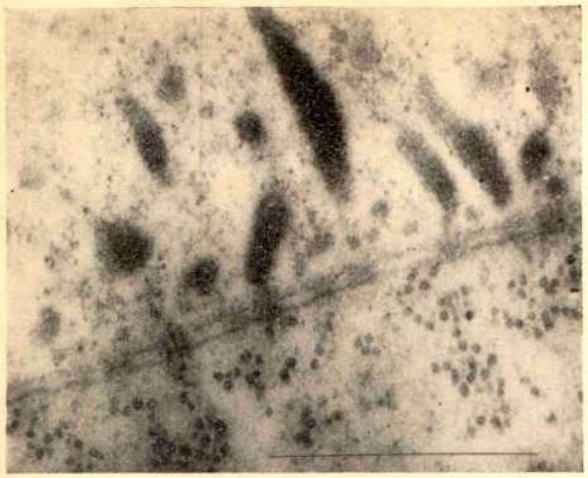

Fig. 1. Electron micrograph showing outflow of material from the nuclear pores of the oocyte of *Rana nigromaculata* (250μ in diameter). Characteristic round particles are shown attached to the lateral loops approaching the nuclear membrane and penetrating its pores, changing their shape into a rod or a thread. Particles within the nucleus remain attached to the lateral loops

Fig. 2. Electron micrograph showing the round particles attached to the lateral loops, near the nuclear pores of the oocyte of *Triturus pyrrhogaster* (150μ in diameter). Particles are shown approaching the nuclear membrane and penetrating its pores, leaving behind their conveyor as a smooth loop

to species differences or are artefactual. Recently, using whole-mount electron microscopic techniques, DuPraw[4] has shown that, in honey-bee embryonic nuclei during interphase, the individual chromosomal fibres are attached to the nuclear envelope, typically at the edge of annuli. Though DuPraw[5] showed that the functional significance of these fibre-annulus attachments is not yet known, these findings are consistent with the present observations.

Fewer flakes near the nuclear envelope are found than might be expected from the large number of granulated patches distributed within the nucleus. This may support the concept of Harris[6–8] that a large part of the nuclear RNA, particularly RNA synthesized on the chromosome, is broken down in the nucleus.

I thank Dr. Mamori Ichikawa for helpful criticism of the manuscript and encouragement throughout the course of the work. This investigation was supported by the Scientific Fund of the Ministry of Education.

GENETICS

Method for the Display of Avian Chromosomes

WHILE chickens and other avian species have been widely used as subjects in many areas of biology, especially embryology, karyological investigations in birds have been restricted because of inherent and procedural difficulties[1]. The relatively large number of small chromosomes seen in birds, the number and morphology of which cannot easily be ascertained, has been one discouraging factor. Another is the fact that the leucocyte culture technique developed by Moorhead *et al.*[2], while generally applicable to mammals, is unsuitable for feral birds. We have found that parasites, which are normally found in the blood, proliferate in culture and interfere with the procedure. This communication describes a simple method for the display of avian chromosomes which has been used with a variety of tissues taken from both praecoces and altrices.

Three to 3·5 h before extirpating the chosen organ or tissue, fertile eggs or young birds were injected with 0·01 mg of colcemide or colchicine (0·1 per cent solution) for each 5 g of mass. When embryos were to be used, the injection was made into the yolk sac; neonates were injected intraperitoneally. The material to be used was finely minced and teased in a drop of Hanks's balanced salt solution in a small Petri dish giving a cell suspension. The suspended cells, but not the larger pieces, were picked up with a pipette and placed in 3 ml. centrifuge tubes and Hanks's solution was added to a final volume of about 2 ml. Sediment was removed from the tubes after standing for 2–5 min.

The tubes were then placed in a centrifuge and spun at 84*g* for 6 min. Without disturbing the cells, the supernatant liquid was removed with a pipette. One to 2 ml. of 0·95 per cent sodium citrate were added and the cells were suspended by aspirating and discharging the suspension with a pipette. After standing for 20 min, the tubes were again spun and the supernatant fluid removed. The cells were suspended in a small amount of fixative (glacial acetic acid–methanol, 1 : 3) after which more was added to a volume of 1·5 ml. Following a 30 min period of fixation, the tubes were spun and the supernatant fluid removed. A small volume of either 45 per cent acetic acid or fixative solution was put in the tubes and the cells were resuspended.

One or two drops of the cell suspension were placed on a clean warmed slide and dried. While drying, the drop was moved around by rotating the slide in order to obtain uniform distribution of the cells. Slides were then stained in acetic–orcein, dehydrated in 95 per cent and 100 per cent ethanol, cleared in xylene and mounted by placing a cover slip over a drop of 'Piccolyte' or 'Permount'.

If the choice of tissue is not dictated by the experiment, it is well to take one undergoing rapid proliferation, at the particular age of the organism to be used. Very early in the period of incubation, the whole embryo is suitable. Good preparations have been obtained from 2 day chicken and 4 day turkey embryos. Following organogenesis, the liver grows rapidly and may be used. From about 11–15 days the spleen is undergoing rapid growth and yields many mitotic cells. During the later stages of incubation of praecoces the bursa of Fabricius and the thymus have been successfully used, while in young chicks, turkeys or pheasants the bursa and bone marrow have been found to be excellent sources of material. Bone marrow is obtained by splitting either tibiae or femora longitudinally and removing the marrow with a blunt probe; it is afterwards handled like other tissues.

We have not attempted to use the embryonic tissues of any altricial birds. However, young sparrows and robins taken from the nest 2–10 days after hatching have been found to be suitable subjects. The best tissues appear to be the bursa of Fabricius and bone marrow.

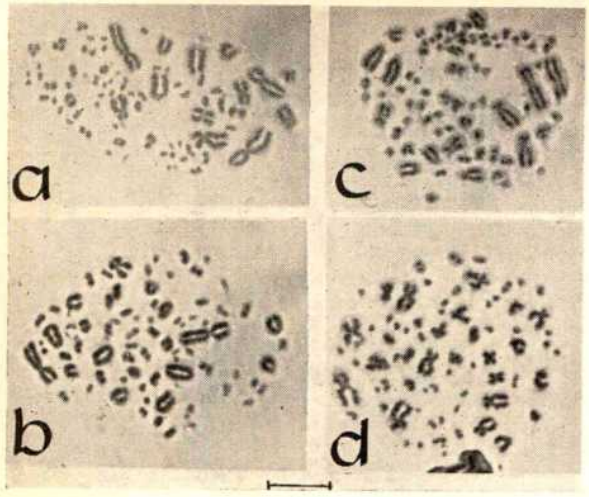

Fig. 1. Photographs of avian metaphase chromosomes. *a*, Chicken, male (*Gallus domesticus*); *b*, ring-necked pheasant, female (*Phasianus colchicus torquatus*); *c*, robin, female (*Turdus migratorius*); *d*, sparrow, male (*Passer domesticus*)

This relatively simple method, which requires no elaborate equipment, may enable a number of investigators to undertake cytogenetic investigations of avian species. The quality of the preparations that has been obtained can be seen in Fig. 1.

Frequency of Colour Blindness among East Kentish Children

AN investigation of the frequency of colour blindness among East Kentish children was made in connexion with research sponsored by the Department of Child Development, Institute of Education, University of London. The *Ishihara Test* (second edition: 24 plates) was used under north daylight conditions, and all the children in five schools were tested. Two of the schools were in the city of Canterbury, two in agricultural communities and one in a Kentish coalfield village. The children ranged in age from 4·5 to 11·0+ years. "Colour blind" responses to 12/16 plates of figures and/or all the "path tracing" plates were required for a diagnosis of colour blindness. The frequencies found were as shown in Table 1.

Table 1

	Boys	Girls
Number tested	505	450
Colour blind	17	0
Percentage colour blind	3·37	0

The children had been tested with the *Kent (Standardised) Tests*. The range of general ability among the colour blind boys ran from 78 I.Q. to 134 I.Q., and no relationship was found between either educational ratio or intelligence quotient and colour blindness.

The frequency of 3·37 per cent of red–green blind boys in East Kent is very low, but accords with the findings of Vernon and Straker[1], who reported 3·55 per cent for Edinburgh, 3·26 per cent for Chesterfield and 4·37 per cent for Romford. Kherumian and Pickford reported 4·12 per cent in the Vosges and Moselle. These are the lowest frequencies reported for Great Britain and France, and they occur in the north and east of Britain and in those parts of France which have the poorest soils and are most removed from the Mediterranean and English Channel coasts, as was pointed out by Post[3] and Pickford[4], in their observations on the possible relaxation of natural selection against colour blindness under the conditions of civilization.

In the present investigation the expected frequencies of colour blind girls would be less than 3·37 per cent[2], namely, about one in 1,000 or fewer, and it is not surprising that none was found in a sample of 450 girls.

I thank Prof. R. W. Pickford and Miss Mary Waddington for their assistance.

RADIOBIOLOGY

Assessment of Body Content of Radioactive Strontium following Contamination in Adult Men

ASSESSMENT of the body content of humans following an accident with radioactive strontium, particularly with strontium-89 or strontium-90, is one of vital concern. Even if equipment for body radioactivity measurement is available, its relatively low sensitivity for these isotopes makes it important to have other rapid and reliable means of estimating the body content. One of us[1] presented a simple relationship between the cumulative urinary excretion of radioactive strontium over 21 days, $\Sigma_0^{21}U$, and the injected dose R_0:

$$R_0 = \frac{\Sigma_0^{21} U}{0{\cdot}6} \qquad (1)$$

It was also shown that following a chronic ingestion of radioactive strontium there was a simple relationship between $\Sigma_0^{21}U$ and the systemic retention at the time of the last ingestion.

It has been pointed out by Macdonald *et al.*[2] that complete collection of urine over 3 weeks has practical difficulties and the inevitable delay in assessment of the body content of radioactive strontium is undesirable. Additional data from experiments in which the gamma-ray emitter, strontium-85, was administered to volunteers from the Radiobiological Research Unit have prompted us to give the problem further consideration. In Tables 1 and 2 we have compared the urinary excretion of radioactive strontium in 5, 10 and 21 days as a percentage of systemic content, R_0. For the intravenous administrations (Table 1) the original dose was taken as the value of R_0, while for the chronic ingestion (Table 2) R_0 was derived from body radioactivity measurements for each subject[3].

It will be seen that the more complete data support the original empirical equation (1). However, the gain in accuracy by extending the urinary collection to 21 days (as judged by the standard errors of the mean values) is small. To make the assessment of body content of radioactive strontium more rapid, it is suggested that the modified formula $R_0 = \frac{\Sigma_0^5 U}{0{\cdot}5}$ following intravenous injection is sufficiently exact for the present requirements.

Samachson[4] and Macdonald *et al.*[2] have attempted to make this assessment from a single observation of the plasma concentration or one day's urine collection respectively, but we feel that such conclusions should not be based on a single observation. However, there will be occasions when incomplete urine collections will be unavoidable, especially when there are difficulties in enlisting the necessary co-operation of the subjects. We have, therefore, examined an alternative approach to the problem. The individual retention equations (each using three exponential functions of time)[5] for five subjects were differentiated with respect to time to give expressions for the excretion rates. From the equation for each subject, values were calculated of the retention, the total excretion rate and the ratio, F = retention/excretion rate, at various times after intake. The ratios are plotted as a function of time in Fig. 1, but to avoid confusion only those parts of the curves which define the envelope of the area enclosed are shown. For times up to 18 days after intake, the empirical equation: $F = 5{\cdot}4\ e^{0{\cdot}13t}$, where t is the time in days after exposure, predicts to within ± 30 per cent the calculated value for each subject.

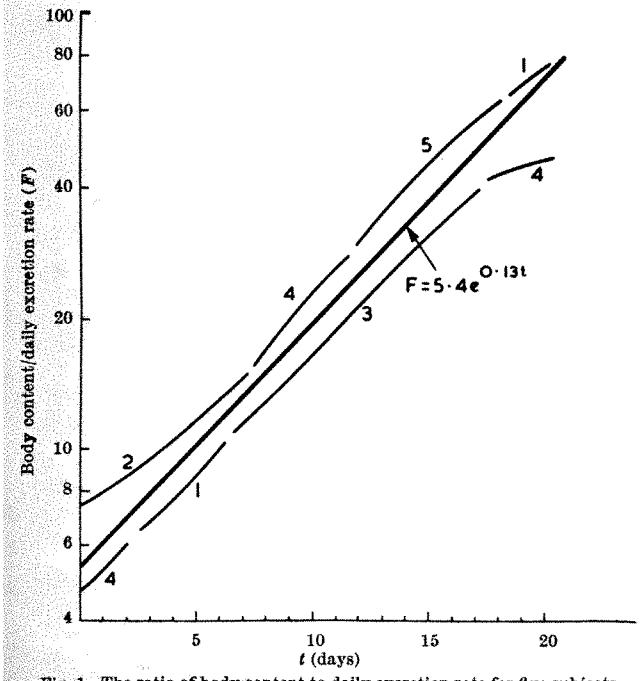

Fig. 1. The ratio of body content to daily excretion rate for five subjects, calculated from individual retention equations. Subjects: 1, T.E.F.C.; 2, G.E.H.; 3, G.R.H.; 4, J.F.L.; 5, F.S.W.

Endogenous faecal excretion is approximately 23 per cent of the total excretion[6], so the expression $7\ e^{0{\cdot}13t}$ may be used to calculate the factor by which the 24 h urinary strontium excretion is to be multiplied to give the systemic content at any time up to 18 days after an intake to the body, irrespective of the route of intake. The uncertainty of not more than 30 per cent is acceptable for purposes of radiological protection and is of the same order as the day-to-day variations in strontium excretion.

Prevention of Nuclear Damage in Irradiated Rat Thymocytes by Post-irradiation Oxygen Deprivation

POST-IRRADIATION exposure of rats to the respiratory inhibitor carbon monoxide has been shown to reduce mortality[1,2]. On the cellular level, respiratory inhibitors (cyanide, high concentrations of nicotinamide) reduce or entirely prevent the usual post-irradiation loss of nuclear structure (pycnosis) when they are added to cultures of highly radiosensitive thymocytes after irradiation[3]. The purpose of this communication is to show that radiation-induced loss of nuclear structure in thymocytes can also be prevented by maintenance of aerobically irradiated cells in an anaerobic environment.

In the initial experiments, ten 5-week-old Sprague–Dawley rats were irradiated with 1,000 r. (dose rate: 100 r. min^{-1}) of 250 kV X-rays produced by a Seifort 'Isovolt' X-ray machine. Ten minutes after irradiation, five rats were killed and their bodies stored in an incubator at 37° C. At various times after irradiation the thymus was removed from one living and one dead rat. Thymocyte suspensions were then prepared (in medium 199). Immediately thereafter the cells were fixed in neutral formalin and stained with Delafield's haematoxylin following the method previously devised by Whitfield *et al.*[4].

Cells with structurally homogeneous nuclei began to appear in the thymuses of the living animals 1 h after irradiation (Fig. 1). By 6 h after irradiation about 85 per cent of the cells had homogeneous nuclei (Fig. 1). In the dead rats, on the other hand, there was very little development of nuclear homogeneity; the majority of the cells contained structurally normal nuclei at 6 h after irradiation (Fig. 1). Even 8 h after irradiation only 4·0 per cent of the cells in the dead animals had homogeneous nuclei while in the living rats 90 per cent of the thymocytes had such nuclei.

Because thymocytes became very fragile after 4 h in the dead rats, the observed difference could have resulted from a differential destruction of damaged cells by the mechanical stresses of the cytological procedure. However, the same results were obtained when unfixed and unstained populations were examined (cells with normal or struc-

Table 1. EFFECT OF ANAEROBIC CULTIVATION ON THE ACCUMULATION OF CELLS WITH HOMOGENEOUS NUCLEI IN IRRADIATED THYMOCYTE SUSPENSIONS

2·0	32·5
3·0	41·7
Aerobic control	74·2

turally homogeneous nuclei could be readily recognized in such untreated preparations).

The striking difference between the rates of radiation-induced nuclear changes in living and dead animals probably arose from the absence of respiration in the anaerobic environment in the dead animal. However, to ascribe the effect to anaerobiosis and not to some other post-mortem phenomenon, we were obliged to show that oxygen deprivation after irradiation could reduce nuclear damage in cultures of thymocytes.

Thymocytes were suspended in a glucose–phosphate medium containing 15 mM sodium monohydrogen phosphate and buffered at *p*H 7·2 with 5·0 mM *tris* (hydroxymethyl) aminomethane. This medium and the method of isolation of thymocytes have been described in detail by Whitfield *et al.*[4]. The kinetics of nuclear homogenization in cells maintained in this medium are identical to those in the living animal. All suspensions were irradiated under aerobic conditions at 37° C with 1,000 r. (dose rate: 100 r. min^{-1}). The oxygen tension in the medium was reduced from the normal level of 3·70 mg/l. to 0·14 mg/l. by initially bubbling nitrogen through the (cell-free) medium and then continuously passing nitrogen through the gas phase of the cell culture during the subsequent period of incubation. Bubbling nitrogen through the culture was avoided as the mechanical stress and anaerobiosis combined to cause a rapid and complete lysis of the cell population.

Reduction of the oxygen tension during the first 3 h after irradiation prevented, or very much reduced, the loss of nuclear structure (Table 1). Transfer of cells to the anaerobic medium as late as 3 h after irradiation could not undo the damage which had already been done but it greatly reduced any further loss of nuclear structure in the population. As an illustration of this, the percentage of cells with homogeneous nuclei in aerobically maintained populations 2 h after irradiation was 26·4 per cent and when the cells were transferred to the anaerobic medium the percentage rose to only 32·5 during the next 4 h (Table 1); under aerobic conditions, the percentage would have risen to 74·2 (Table 1). Three hours after irradiation, the percentage in the aerobically maintained population had risen to 39·3 and when the cells were transferred to the anaerobic medium the percentage rose to only 41·7 during the next 3 h (Table 1).

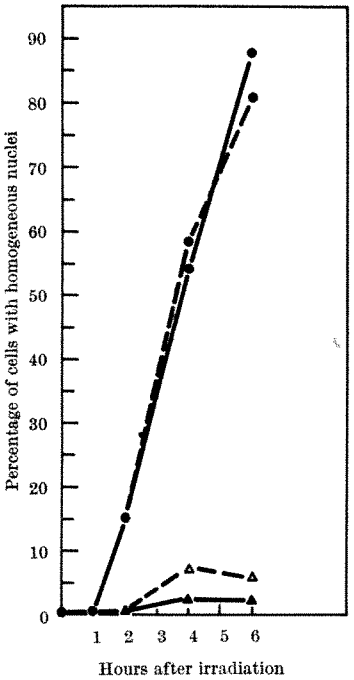

Fig. 1. The accumulation of cells with structurally homogeneous nuclei in the thymuses of living and dead irradiated (1,000 r.) rats. ●———●, In living rat, stained preparations; ● - - - - - ●, in living rat, unfixed and unstained cells. ▲———▲, In dead rat (killed 10 min after irradiation), stained cells; △ - - - - - △, in dead rat, unfixed and unstained cells

We conclude now that oxygen deprivation after irradiation can reduce the amount of nuclear damage in very radiosensitive cells such as thymic lymphocytes which when irradiated suffer an early death in interphase. An identical effect has been observed in preliminary experiments with the equally radiosensitive bone marrow. The effectiveness of oxygen deprivation for a relatively long time after irradiation under aerobic conditions rules out any involvement of the classical oxygen effect (reduction of the number of oxidizing radicals formed during radiation in the absence of oxygen).

On the bases of cytological[4,5] and biochemical[6–8] observations the post-irradiation loss of nuclear structure in thymocytes can be attributed to a phosphate-induced separation of histones from the deoxyribonucleic acid of the interphase chromatin. Such a separation would cause the highly condensed nucleoproteins of the chromatin granules and threads of the interphase nucleus to disaggregate into a structureless, basophilic mass[4,8].

During the first hour after irradiation, the ability of the thymocyte nucleus to synthesize oxidatively adenosine triphosphate is inhibited[9,10] while the uptake of inorganic phosphate and respiration are unaffected at this time[3,10]. The free phosphate which enters the nucleus can dissociate the histones from the irradiated (and certainly unstable[11]) deoxyribonucleoproteins[8]. Because phosphate uptake by such cells is propelled by respiration[12], any agent or condition which stops or slows respiration would be expected to prevent, or at least reduce, the loss of nuclear structure. This has already been shown to be true using respiratory inhibitors[3], and the present observations fully support this expectation.

Radiation-induced Calcium Release and its Relation to Post-irradiation Textural Changes in Fruits and Vegetables

Loss in texture is the most characteristic change in fruits and vegetables on exposure to ionizing radiation[1–9]. Relatively low doses induce extensive softening in tissues. Consideration of the radiation-induced chemical changes in pectins—important structural elements of the middle

lamella[10]—led to the suggestion that their *in situ* degradation may contribute to softening[11]. A decrease in protopectin and an increase in the pectin and pectate fractions of pears and peaches irradiated with 300, 600, or 900 krads of γ-radiation have been correlated with textural changes[12]. Glegg and Kertesz[13] considered that degradation of cellulose was probably a major factor in post-irradiation softening.

Although, in biological adhesion, the role of certain divalent cations, especially calcium, has long been known, it has received little attention in investigations of radiation-induced textural changes. Adhesion of cells has been reviewed in detail by Weiss[14]. Even though the data presented are, for the most part, based on animal tissue, many of them are relevant to plant tissue. Gelation is known to occur on addition of calcium ions to alginate sol; this results in cross-linking of molecular chains through the coulombic forces which exist between the free carboxylic group and the divalent calcium ion. The dependence of the strength of a gel on the concentration of calcium present is strikingly illustrated by data provided by Blood[15]. The middle lamella is considered to be a gel composed largely of insoluble calcium salts of pectic and low methoxyl pectinic acids. Other ions, forming sparingly soluble pectates, could be involved which stabilize the intercellular gel. Also, other substances of macromolecular origin certainly contribute to intercellular bonding. The evidence for the part played by divalent cations in intercellular bonding was provided by Letham[16,17]. The separation of cells from plant tissues on treatment with ethylenediamine tetraacetate (EDTA) or hexametaphosphate (HMP) was shown to be largely dependent on the chelation of calcium and possibly magnesium ions. After treatment with HMP, shaking results in considerable separation of cells from apple tissue. Addition of either divalent or trivalent ions before shaking results in the cells becoming recemented.

This communication describes the release of calcium from *Avena* coleoptiles and from peaches irradiated over a dose range of 50–1,000 krads. Irradiations were carried out at ambient temperatures. After irradiation, the tissues were transferred to a dialysing bag and suspended in conductivity water (190 ml.) and shaken (100 strokes per min). Changes in specific conductivity were measured with a conductivity bridge. Compared with the controls, the irradiated tissue very rapidly lost electrolyte, as was shown by increases in conductivity. In exploratory experiments, calcium was detected by reaction with glyoxal-*bis*-2 hydroxy-anil reagent and extraction with chloroform; the appearance of a red colour in the organic phase indicating the presence of calcium[18]. In quantitative experiments, the combined dialysate and washings from the dialysing bag were evaporated to dryness. The residue was digested with a mixture of perchloric and nitric acids (3 : 1), 5 ml. On evaporation to dryness, the residue was dissolved in water and diluted to 25 ml. The amount of calcium released was measured by the standard flame photometric method[19]. The amount of calcium retained in the tissue was proportional to the dose up to 600 krad, after which about 80 per cent of it was released. If the dose was increased beyond 600 krads, there was no significant increase in calcium release. This observation could be significant in investigations concerning the nature of intercellular bonding. The calcium release induced by irradiation is probably independent of enzymatic mediation. Irradiation at 0° C did not decrease the calcium release over the dose range investigated.

Experiments at the University of Michigan[20] with tomato leaves which had absorbed calcium-45, and with detached strawberries which had been stem-fed with the same isotope, independently substantiate these results.

Release of calcium also occurred in model experiments in which calcium pectate was suspended in water and irradiated. Furthermore, a certain degree of decarboxylation was observed on irradiation of a pectic acid–water suspension, as was evinced by the reduction in neutralization number. Such results indicate that the electrovalent links between calcium or other divalent cations and the carboxyl groups of pectic acid are broken on irradiation. This could result in loss of adhesion between cells of a tissue. Even though covalent bonds exist in the middle lamella which possibly hold together other macromolecules, it can be concluded that the release of calcium plays an important part in radiation-induced softening of fruit and other plant tissue. A complete release of calcium is probably not obtained because of its involvement in other modes of combinations.

Although no explanation was offered by Somogyi and Romani[12] for the relatively reduced softening of tissue in a nitrogen atmosphere, it is likely that in aerobic irradiation ozone and free radicals associated with the presence of oxygen are more critical factors. A period of anaerobiosis will rapidly increase the covalent bonding, which in turn will affect the strength of the tissue concerned[21,22].

Strontium-90 in Beagle Hair

IN 1963, Hopkins *et al.*[1] reported the accumulation of significant amounts of strontium-90 in the hair of rats which had acquired known body burdens of the radionuclide either by injection or *in utero*. They further suggested that the analysis of hair could provide a non-destructive method of measuring bone seeking radioelements. The Davis Beagle Project offered a unique opportunity to test this hypothesis as the diet and the gut-kidney discrimination factors are well controlled and known. Accordingly, we assayed the concentration of strontium-90 in the hair of beagles while the animals were on a chronic ingestion regimen of the radionuclide, at constant ratios of strontium-90 : calcium, as well as afterwards. The concentration of strontium-90 in the hair was followed up to 1 year after we stopped feeding the diet containing strontium-90, and was correlated with the ratios of strontium-90 : calcium for plasma during the same periods.

Table 1. STRONTIUM-90 IN BEAGLE HAIR

Level*	No. dogs	g Ca/g ash	μc.^{90}Sr/g Ca			Observed ratio†	
			Hair	Plasma	Diet	Hair/plasma	Hair/diet
D3	3	0·12	0·16	0·17	0·35	0·9	0·46
D4	1	0·13	0·31	0·30	1·11	1·0	0·28
D5	12	0·12	1·38	1·33	3·20	1·0	0·43
Mean		0·12				1·0	0·42
Range		(0·11–0·15)				(0·6–1·5)	(0·23–0·65)

* The dietary levels *D3*, *D4*, *D5* are maintained at a 1 per cent calcium content (by weight) with a calcium/phosphorus ratio of 1·5 and a three-fold increment in the ratios of strontium-90 : calcium.

† The value of the observed ratio is given by the $\frac{\text{Sr-90/Ca sample}}{\text{Sr-90/Ca precursor}}$

Samples of beagle hair (5–20 g) were obtained by clipping the hair of the lower neck and upper chest, and in a few cases hair was taken from the flanks. Repeat samples of hair were obtained from the same areas at about 100-day intervals, or when hair regrowth had completely blended with the surrounding hair. The hair was weighed dry, washed with water containing a detergent, and rinsed with tap water, then deionized water, and finally 1 N hydrochloric acid. After drying, the hair was ashed at 600° C for about 12 h, weighed and dissolved in 1 N hydrochloric acid to a standard volume. The strontium-90 and calcium content of hair and plasma were determined on the ashed samples using methods described earlier[2].

The deposition of dietary strontium-90 in the hair of beagles during exposure to three ingestion levels of the radionuclide is shown in Table 1. The calcium content of hair is about 12 per cent of the ash weight, or 0·04 per cent of the fresh weight. During the course of the chronic ingestion of the radionuclide, the ratios of strontium 90 : calcium for the plasma and hair are essentially equal and constant. The strontium-90 : calcium ratios of plasma relative to those of the diet represent an overall reduction by a factor of more than two resulting from the combined gastro-intestinal and renal discriminatory processes[3]. The value of the observed ratio of bone : diet in the beagle has been found to be about 0·45. Thus, it seems that the ratio of strontium-90 : calcium for plasma governs the ratio of strontium-90 : calcium for other compartments, that is, hair and bone, unless there are other intermediate and intervening membrane barriers which result in further discrimination, as in the placenta or mammary gland.

The relative specific activities, in μc. strontium-90/g calcium, of plasma and hair during and after the chronic ingestion of strontium-90 are shown in Fig. 1. The data for all dogs are presented as mean values and ranges which have been normalized to the highest ingestion level (*D5*) by multiplication of the values by the appropriate factors which separate the strontium-90 concentrations of the different dietary levels. Thus, the ratios of strontium-90 : calcium for hair and plasma were nearly constant at 1·5 μc. strontium-90/g calcium with the observed ratio of 0·45 for all dietary levels.

After we stopped feeding the diet containing strontium-90, there was a rapid decrease in the strontium-90 : calcium ratio of plasma to a normalized value of 0·1 μc. strontium-90/g calcium at 200 days after feeding the animals the radionuclide (740 days of age). In contrast, the ratio of strontium-90 : calcium for hair obtained at consecutive 100-day intervals was consistently greater than that of plasma taken at the same time, so that at 1 year after feeding with strontium-90 the ratio of strontium-90 : calcium for the hair was about 1·5–2 times higher than that for the plasma.

Because of the integral nature of hair growth, the ratios of strontium-90 : calcium for hair and bone will demonstrate similar relative specific activities during the chronic feeding of the radionuclide and, following the end of feeding, the ratios of strontium-90 : calcium for hair will reflect the continually decreasing relative specific activities of plasma during the period of growth. Furthermore, the hair : plasma ratio will increase as a function of the interval between clippings if the plasma is sampled at the time of clipping. However, if the plasma were sampled at the midpoint of the growth period these differences would be considerably smaller.

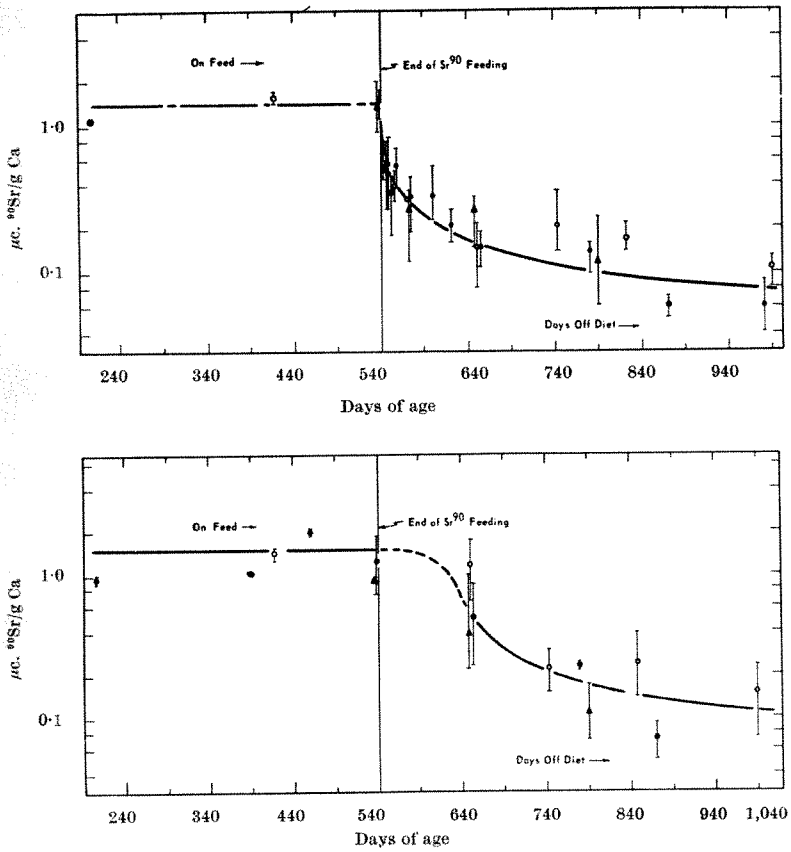

Fig. 1. Mean normalized "*D5* level" plasma (top) and hair (bottom) concentrations, μc. strontium-90/g calcium, while on strontium-90 feed and following the end of the period during which strontium-90 was fed to the animals. Mean values and ranges for each ingestion level obtained from six dogs *D3* level (○); eleven dogs *D4* level (▲); and nine dogs *D5* level (●)

The accumulation of strontium-90 in hair during periods of exposure to the radionuclide affords the opportunity of estimating the strontium-90 concentration of the diet. If all the factors in the metabolism of strontium relative to its transfer from diet to blood, and then to bone and hair, are fully understood, this form of non-traumatic bio-assay offers a less variable approach to strontium-90 contamination investigations than either excreta or diet investigations. The usefulness of hair in a bio-assay method could be extended to other radionuclides, for example caesium-137, as a possible index of body burden and dietary concentration.

In the Davis experimental beagles, the constant relationships between the ratios of strontium-90 : calcium in the diet, plasma, bone, and hair during the period of continual strontium-90 feeding affords an estimate of the strontium-90 concentration in the body. When the dog is taken off the dietary strontium-90, the uniformly labelled skeleton provides an endogenous source of the radionuclide, by way of the plasma to the hair, and thus supplies an indirect assessment of that portion of the skeleton which undergoes remodelling during the period of hair growth.

SOIL SCIENCE

Fluoride Interaction with Clays in Relation to Third Buffer Range

Considerable acceptance of a ready exchange of structural OH of clay minerals by fluoride ions has been reported[1]; however, so far the evidence rests mainly on the appearance of OH in an extraction solution of potassium fluoride. Recently it was found[2] that the hydrochloric acid titratable OH formed on the reaction of clay minerals and soils in neutral 1 N potassium fluoride solution results from the complexing reaction by fluoride ions and dissolution of structural aluminium or iron from the minerals, by a reaction that can be represented as:

$$Al(OH)_3 + 6KF \rightarrow K_3AlF_6 + 3KOH \qquad (1)$$

No fluoride that could be analytically detected remained in the clay or soil sample. A series of carbon replicas of micas shows (Fig. 1) that biotite and muscovite surfaces are disrupted by the reaction in neutral 1 N potassium fluoride solution for 12–24 h. Furthermore, potentiographic evidence reveals that, on disruption of the surfaces of the sesquioxic and the alumino-silicate minerals, acidic functional groups such as $^{4}X\text{Al–OH}_2$ and $X\text{Fe–OH}_2$ develop in the minerals and this results in the appearance of a third buffer range[5]. This indicates that the third buffer range not only arises from the neutralization of excess protons of Al–OH_2 groups in the positively charged hydroxy aluminium polymers formed in the interlayer surfaces of expansible clays, but also from sesquioxic surfaces in general. The reaction of the titrating base with the substituted hydronium surface or edge groups ($X\text{M}^{3+}\text{–OH}_2$) of the oxides of iron, hydroxide of aluminium and the alumino-silicates (including allophane) is as large as 50–100 m.equiv./100 g. This third buffer range is of considerable importance in mid-range soil acidity and agricultural liming practice as well as in the retention of sodium in alkaline soils.

The present investigation showed that third buffer range developed in the titration with sodium hydroxide of $Al(OH)_3$ (Merck) and natural gibbsite ($< 20\mu$) treated with potassium fluoride could be reversibly titrated with hydrochloric acid (Fig. 2, *b* versus *c*). After the reaction of sodium hydroxide with the proton–donor groups on the natural gibbsite treated with potassium fluoride, the mineral suspension was sedimented by centrifugation and washed five times with an ethanol–water mixture as is usual in the measurement of cation exchange capacity. The third buffer range again appeared in the sodium hydroxide titration of the washed residue (Fig. 2*d*), which shows that the sodium is only weakly held and readily hydrolysed in water. These results further strengthen the argument that the third buffer range which appeared in the sodium hydroxide titration curves of minerals made to interact with potassium fluoride resulted from the neutralization of the proton–donor groups on the mineral surfaces[2,4], and proceeded by way of equation (2):

$$\text{Mineral Al (or Fe)} \begin{matrix} \text{OH}_2^{0.5+} \\ \text{OH}^{0.5-} \end{matrix} + \text{NaOH} \longrightarrow$$

$$\text{Mineral Al (or Fe)} \begin{matrix} \text{OH} \\ \text{OH} \end{matrix} \text{Na} + \text{H}_2\text{O} \qquad (2)$$

In addition, fluoride-saturated 'Dowex 21*K*' (*RF*) was used to interact with the hydrogen–aluminium vermiculite (2–0·2μ in diameter). The mixture of clay and 'H–Amberite, *IR* 120' (*HR*) was shaken for 2 h, while that of clay and *RF* was shaken overnight. The clay suspension was separated by suction on a glass filter. Potassium

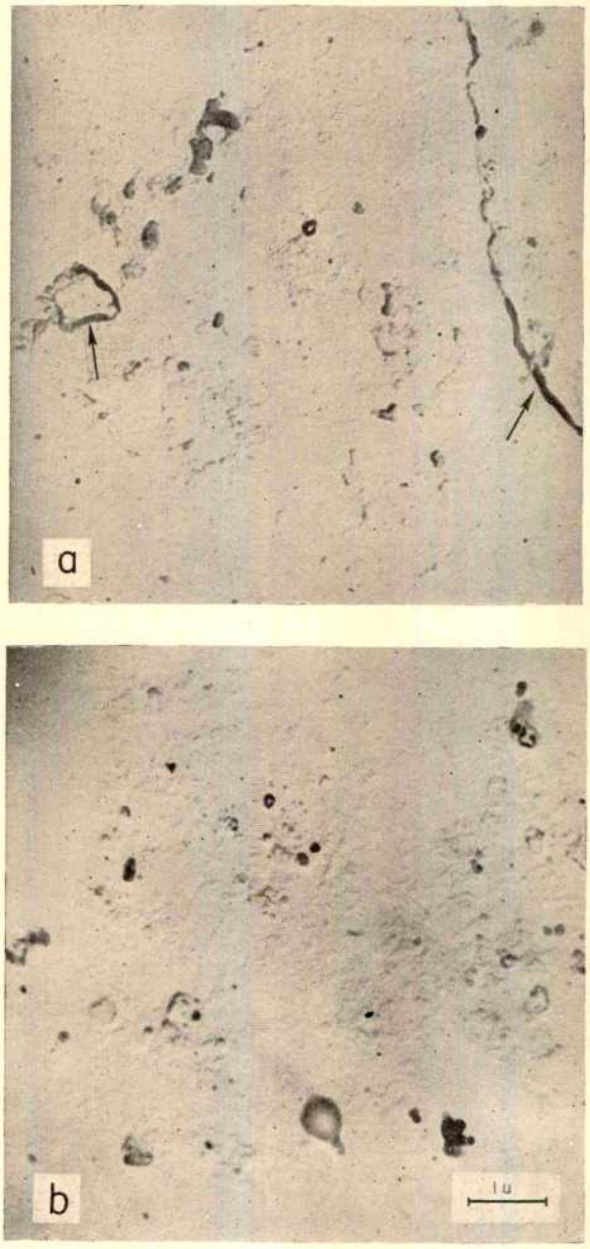

Fig. 1. Electron micrograph of carbon replica of the cleavage surfaces of (*a*) biotite and (*b*) muscovite, showing the corrosion and fractures caused by interaction with neutral 1 N potassium fluoride for 12 and 24 h, respectively. Scrolling (arrows) results from fractures as shown by Raman and Jackson (ref. 3), together with smooth untreated biotite and muscovite cleavages. (We thank Charles Roth for his assistance in the electron microscopy)

nitrate was then added to make 1 N potassium nitrate and 0·5 per cent clay in the suspension. The suspension was shaken for 1 h before it was titrated with sodium hydroxide. (The titration apparatus used was a Metrohm potentiograph; the speed of titration was 0·0065 m.equiv./min.) The titration curves (Fig. 3) show that the total base consumption of the clay, created by *HR* interaction, was one-third reduced on the interaction of *RF*. This can be attributed to the removal from the clay of aluminium or iron that can be complexed to form fluoraluminate or fluorferrate[6] in solution, and to release OH which then reacts with part of the acid clay. The decrease in acidity of the hydrogen–aluminium clays by *RF* interaction is compensated on treating them again with *HR*—

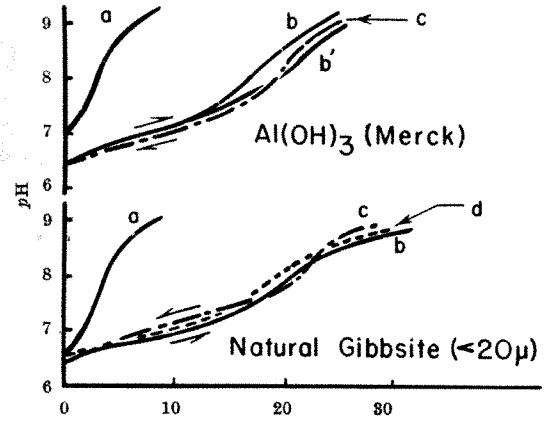

Fig. 2. Potentiograms showing the effect of fluoride treatment on the titration curves of gibbsite suspended in 1 N potassium chloride. *a*, Control, with no potassium fluoride treatment, sample washed with potassium chloride and then with water–ethanol, and then titrated with sodium hydroxide. *b*, Sample washed with potassium chloride, reacted with neutral 1 N potassium fluoride for 24 h, and then washed with water–ethanol and titrated with sodium hydroxide. *b'*, Duplicate of *b*. *c*, Sample treated as in *b* and then back titrated with hydrochloric acid (curve plotted backward, arrows). *d*, Sample treated as in *b* then washed with water–ethanol and titrated again with sodium hydroxide, showing that the full acidity was restored by hydrolysis during washing

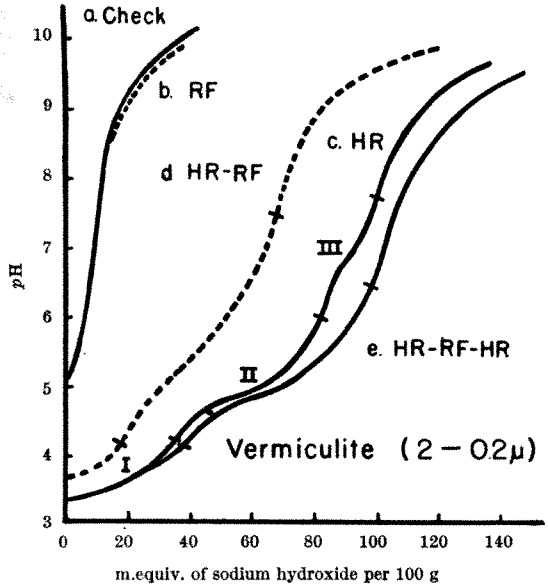

Fig. 3. Potentiograms showing the influence of hydrogen resin (*HR*) and fluoride resin (*RF*) treatment on the sodium hydroxide titration curves of vermiculite suspended in 1 N potassium nitrate. *a* and *b*, Controls, with no treatment with *HR* and *RF* for (*a*) and sample (*b*) showing no reaction with *RF* during 24 h. *c*, Sample reacted with *HR* for 2 h. *d*, Sample treated as in *c* and then reacted with *RF* for 24 h. *e*, Same as *d* followed by another treatment with *HR*; note that the third range has been removed by the *RF* treatment (curve *e* compared with curve *c*)
Proton donor ranges: I, OH_2^+; II, $Al(OH_2)_6^{3+}$; III, $[Al_x(OH)_{3x-n}(OH_2)_m]^{n+}$

through saturation of all cation exchange sites of the clay with hydrogen (and aluminium released the spontaneous alteration[7] of hydrogen clays to aluminium clays).

The results obtained in the present investigation indicate that the interaction of fluoride resin with hydrogen–aluminium clays brings about the removal of acidic functional groups from the minerals, particularly the third range (Fig. 3, curve *e*). In contrast, the reaction of neutral 1 N potassium fluoride resulted[2] in the formation of the proton–donor groups on the mineral surfaces of the third range. The *RF* action is considered to be predominantly that of removal of polyalumina which readily forms[5,8] in acid vermiculite, while the potassium fluoride rapidly removes trivalent ions from the structure, which creates weakly acidic XM^{3+}–OH_2 groups on the surfaces and at the same time forms an excess of potassium hydroxide (*p*H 8–11) by equation (1). We attribute the third range buffering[5] (Fig. 3), which resulted from treatment of aluminosilicate clays with *HR*, to alumina surface groups rather than to aluminosilicate surface characteristics. This conclusion is based on the large third range buffering which arose on the surfaces of pure iron oxides and alumina[2] (Fig. 2) in the absence of a silica component.

Toxicity of Boron to Rice

IN the course of a study on the chemical retardation of soil reduction as a remedy for physiological disorders of the rice plant, we observed that despite this retardation by calcium nitrate and manganese dioxide the foliar symptoms persisted in one of the four soils studied.

The symptoms were intervenal chlorosis of the upper portions of the older leaves, especially along the margins, and later large dark brown elliptical spots in the affected parts which ultimately turned light brown, dried and rolled up. They were almost identical with the symptoms of boron poisoning in rice grown in culture solution as described by Lockard[1]. The boron content of the straw at harvest was 80 p.p.m. compared with 26–30 p.p.m. for normal plants.

The soil was a saline silt loam from the Silo region on the coast of Taiwan and had a *p*H of 8·1. Soil solutions of the flooded soil contained 9·1 p.p.m. boron (this figure contrasts with 1 p.p.m. boron for two normal Philippine lowland rice soils).

To ascertain whether the symptoms observed in the Silo silt loam were indeed those of boron toxicity, the same variety of rice was grown on two lowland rice soils (Maahas clay—*p*H, 6·6; organic matter, 2·0 per cent and Luisiana clay—*p*H, 4·6: organic matter, 4·1 per cent treated with 0, 20, 40 and 60 p.p.m. of boron given in the form of borax and on untreated Silo silt loam.

Table 1. INFLUENCE OF ADDED BORON (AS BORAX) ON THE CONCENTRATION OF WATER-SOLUBLE BORON (P.P.M.) AND THE SEVERITY OF SYMPTOMS OF BORON TOXICITY TO RICE ON THREE SOILS

Soil	Added boron as p.p.m. of the dry soil							
	0		20		40		60	
	Boron	Symptoms	Boron	Symptoms	Boron	Symptoms	Boron	Symptoms
Silo silt loam	9·1	Moderate	—	—	—	—	—	—
Maahas clay	0·9	None	9·3	Slight	17·6	Moderate	25·6	Marked
Luisiana clay	0·6	None	6·7	Moderate	12·9	Marked	20·1	Very marked

Within a week, the symptoms characteristic of boron poisoning in solution culture were observed in the plants treated with 60 p.p.m. boron. The same symptoms, but in a milder form, appeared a week later in plants grown in the untreated Silo silt loam and in those grown in the Maahas and Luisiana soils treated with 20 and 40 p.p.m. boron. The foliar symptoms observed on plants grown on Silo silt loam were comparable with those on Luisiana soil, to which 20 p.p.m. boron or 6·7 p.p.m. water-soluble boron had been added. Table 1 shows that, although the concentration of water-soluble boron was lower in Luisiana clay than in Maahas clay at all levels of added boron, the toxic effects were more severe in the former. This means that the critical toxic concentration of water-soluble boron for rice may vary from soil to soil.

As coastal soils derived from marine sediments may contain from ten to fifty times as much boron as inland soils[2], boron poisoning may be a hitherto unsuspected factor limiting rice production on such soils.

AGRICULTURE

Identification of Gibberellins A_4 and A_7 in Immature Apple Seeds

FOR many years, plant physiologists have attempted to isolate and identify the growth substances which control plant growth. Many early attempts failed, largely because of the minute quantities of these compounds present in plants. Recently, microtechniques such as thin-layer chromatography have greatly stimulated interest in their identification.

Luckwill[1] investigated the auxins present in apple seeds, but did not identify them chemically except to report the absence of indole-acetic acid[2]. Nitsch[3] demonstrated the presence of gibberellin-like substances in apple seeds, and Kato and Ito[4] extracted such substances from apple shoots. On the basis of relative mobility values for the gibberellins in paper chromatography, MacMillan *et al.*[5] postulated that the apple seed gibberellins demonstrated by Nitsch might be A_5 and A_9.

In an attempt to identify some of the growth substances present in apple seeds, approximately 2 tons of fruitlets of the 'Golden Delicious' variety were collected from a commercial orchard south of Paris between June 14 and 26, 1961. At this time, the fruitlets were approximately 3·5 cm in diameter. The fruitlets were kept in storage at a temperature of 3° C until the seeds could be removed, a process requiring 5 weeks from the first date of collection.

The bioassays used to detect gibberellin activity in the extract were the *Avena* mesocotyl test[6,7], the dwarf pea test[8], the lettuce hypocotyl test[9,10], and the cucumber hypocotyl test[11–13]. The *Avena* mesocotyl test was performed as described by Nitsch and Nitsch[6].

Pea seeds, variety 'Little Marvel', were planted in soil in the greenhouse, 50 μl. of the solutions to be bioassayed were applied to the first true leaf 6–8 days after planting, and the first three internodes above this leaf were measured 5 days after treatment.

Lettuce seeds, variety 'Parris Island', were placed on filter paper disks in vials 19 mm in diameter containing 0·3 c.c. of the solution to be bioassayed. The hypocotyls were measured after 5 days of continuous illumination (450 ft.-candles) at 25° C and 100 per cent relative humidity. Ten hypocotyls were measured in each of two vials for each treatment.

Cucumber seeds, variety 'Spartan 27', were germinated on moist filter paper under continuous light (450 ft.-candles) at 25° C and 100 per cent relative humidity. After 3 days, the seed coats were removed and the seedlings planted in vermiculite under the same environmental conditions. Twenty-four or 48 h after transplanting, 20 μl. of the solutions to be bioassayed were applied to the epicotyl and adjacent cotyledons, and the length of the hypocotyl measured 2 days after treatment.

'Tween 80' (0·1 per cent) was included as a surfactant in all solutions, and all control plants were treated with this concentration of 'Tween'.

On removal from the fruits, the seeds were dropped into cold methanol and transferred to a freezer at −20° C. The seeds were ground and extracted repeatedly with fresh methanol, the methanol filtered through paper and evaporated *in vacuo*, and the tissue discarded. The aqueous residue remaining after removal of the methanol was frozen and lyophilized. The residue was dissolved in water, the *p*H adjusted to 3·0 with hydrochloric acid, the solution exhaustively extracted with diethyl ether, and the water phase discarded. The ether was evaporated *in vacuo* and the residue chromatographed (ascending) on 'Whatman No. 17 filter paper using isopropanol/water/ammonia (80:19·9:0·1) as the developer. The area of the chromatograms active in the *Avena* mesocotyl test (R_F 0·5–1·0) was eluted with 80 per cent methanol. The solvent was removed *in vacuo*, and the residue chromatographed in batches on a column of silica gel 22 mm in diameter and 140 mm long, using increasing concentrations of secondary butanol in hexane, both solvents having been previously equilibrated with 0·5 formic acid[14]. Two hundred and fifty c.c. of each of the following solvents were used in elution: 0·5, 10, 25, and 100 per cent secondary butanol in hexane. The first 75 c.c. of the 10 per cent solvent contained approximately one-half of the gibberellin activity (dwarf pea test). This fraction (fraction *A*) was reduced to dryness *in vacuo*, the residue dissolved in water, and the suspension, containing a green precipitate, filtered. The filtrate was evaporated to dryness, and the residue extracted with ethyl acetate. The ethyl acetate fraction, containing the major part of the gibberellin activity, was reduced to dryness (fraction *B*.

Table 1. ELUTION PATTERN OF GIBBERELLINS IN COLUMN CHROMATOGRAPHY ON SILICA GEL

Gibberellin	Solvent (percentage of *sec*-butanol in hexane)				
	0·5	5	10	25	50
A_1				X	
A_2				X	
A_3				X	
A_4		X			
A_5		X	X		
A_6		X	X		
A_7	x	X	x		
A_8					X
A_9	X				
Fraction *A*		X	x		

Activity detected by bioassay of eluates in dwarf pea test. *X*, major activity; *x*, minor activity.

Table 1 compares the elution patterns of the nine gibberellins with that of fraction *A* in column chromatography on silica gel as described above, with the following modifications: column 14 × 140 mm; 100 c.c. per solvent. The residue from each solvent was bioassayed, using the dwarf pea test. The gibberellin activity in the extract coincided with that of gibberellins 4, 5, 6, and 7, which could not be separated with this series of solvents. Activity was clearly separated from that of the remaining five known gibberellins.

Table 2. COMPARISON OF ACTIVITIES OF NINE GIBBERELLINS AND FRACTION *B* IN THREE BIOASSAYS
Height in millimetres

Gibberellin*	Bioassay: Dwarf pea	Lettuce hypocotyl	Cucumber hypocotyl
A_1	57 *cd*	6 3 *c*	24*a*
A_2	42*ab*	4·1*a*	27*a*
A_3	90 *e*	9 9 *e*	27*a*
A_4	42*ab*	8·1 *d*	48 *c*
A_5	48 *bc*	7·5 *d*	26*a*
A_6	44*ab*	5·2 *b*	23*a*
A_7	67 *d*	11·9 *f*	56 *d*
A_8	38*ab*	3 6*a*	24*a*
A_9	36*ab*	5·9 *bc*	37 *b*
Fraction *B*†	44	9·5 *e*	37 *b*
Control	30*a*	3 5*a*	25*a*

* Each gibberellin used at 3×10^{-10} moles per plant (pea and cucumber) or per tube (lettuce).
† Used at 1 g equiv. per plant or tube (lettuce and cucumber) and at 0·56 and 5·6 g equiv. per plant (pea). Value for pea test adjusted to 1 g equiv. per plant by interpolation on semi-log scale.
abcdef, Means not followed by the same letter are significantly different from one another at the 5 per cent level.

The activity of fraction *B* is compared with that of the nine gibberellins in three bioassays in Table 2. The extract was active in all three assays, but activity in the cucumber hypocotyl assay is particularly noteworthy, since both A_4 and A_7 are active, while A_5 and A_6 are not. Hence it appeared that the unknown was either A_4 or A_7.

In order to characterize further the unknown, thin-layer chromatography was used according to the method of MacMillan and Suter[15]. Silica gel *G* was used as the adsorbent, and benzene–acetic acid–water (8 : 3 : 5) as the solvent. Plates 150μ thick were equilibrated over the lower phase overnight, then developed with the upper phase at 25° C. Gibberellins were detected by spraying the plates with 5 per cent sulphuric acid in 95 per cent ethanol, heating for 15 min at 110° C, and noting the pattern of fluorescence under ultra-violet light. Considerable variability was encountered from one set of plates to another using this system. Each set of plates was first checked with a mixture of gibberellins A_4 and A_7 to assure that separation would occur. When separation was obtained, a sister plate was used to compare the R_F's of the known gibberellins with that of the apple gibberellin(s).

Fig. 1 shows the appearance of such a plate after spraying with the reagent and heating. The extract contained two distinct fluorescent areas corresponding closely with the R_F's of gibberellins A_4 and A_7 and separated clearly from gibberellins A_5 and A_6. Additional weak fluorescent

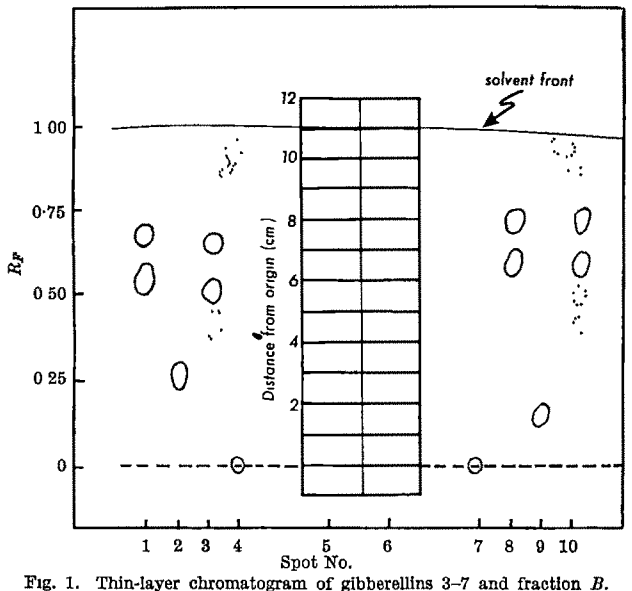

Fig. 1. Thin-layer chromatogram of gibberellins 3–7 and fraction *B*. Spots 1, 5 and 8, mixture of GA_4 and GA_7, 0·4 μg total per spot; 2, GA_5, about 1·0 μg; 3, 6, and 10, fraction *B*, 10 g equiv. per spot; 4 and 7, GA_3, 0·4 μg per spot; 9, GA_6, about 1 0 μg. Centre area covered by glass plate before spraying with 5 per cent sulphuric acid in ethanol and heating. Areas which fluoresced under ultra-violet light after heating are indicated by circles

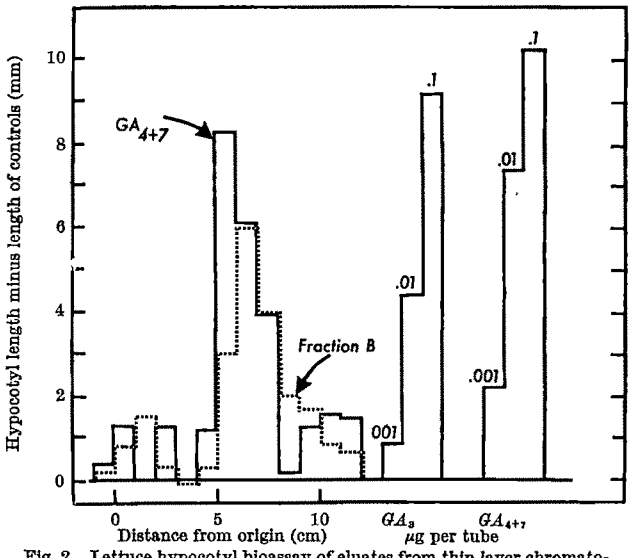

Fig. 2. Lettuce hypocotyl bioassay of eluates from thin layer chromatogram of GA_{4+7} (solid line) and fraction *B* (broken line)

areas appeared just below the position of GA_7 and near the solvent front. The central portion of the chromatogram, to which (*a*) the unknown, and (*b*) a mixture of gibberellins A_4 and A_7 were separately applied, was covered with a glass plate before spraying, and the edges sealed with tape. After spraying, sections of silica gel 1 cm in height by 2 cm in width were scraped from the plate (Fig. 1) and individually extracted with 1 ml. of 0·1 per cent 'Tween 80'. The eluates were filtered, the filtrates frozen and lyophilized, and the residues dissolved in 1 c.c. of water. These solutions were bioassayed in the lettuce hypocotyl test, using 0·3 c.c. of each solution, and the mean length of ten hypocotyls is shown graphically for each section in Fig. 2. Gibberellin activity occurred at the R_F's of A_4 and A_7 in both the extract and in the GA_{4+7} mixture, although the width of the sections used did not allow for separation of the two in the bioassay. The other fluorescent zones in the extract were inactive. The unknown is therefore a mixture of A_4 and A_7.

Since gibberellin activity is not confined to the fractions described above, work is continuing in an attempt to identify some of the more polar gibberellin-like substances present in the extract.

We thank the Pépinières Thuilleaux for the apple fruitlets, Dr. P. W. Brian and Dr. J. MacMillan for samples of gibberellins A_1 to A_9, and Abbott Laboratories, North Chicago, Illinois, for a larger quantity of gibberellin A_3. This investigation was supported in part by a grant from the National Science Foundation.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

RESEARCH ASSISTANT (preferably with a degree or equivalent qualification in biochemistry) to work on nucleic acid metabolism in cancer tumours—The Assistant Secretary General (S5), Brunel University, Woodlands Avenue, Acton, London, W.3 (August 19).

SENIOR LECTURER IN THE DEPARTMENT OF BACTERIOLOGY—The Registrar, The University, Liverpool, 3, quoting Ref. CV/169 (August 19).

ASSISTANT LECTURER or LECTURER IN VETERINARY MEDICINE (Small Animals)—The Registrar, The University, Liverpool, quoting Ref. CV/177/N (August 20).

JUNIOR RESEARCH FELLOWS (2) IN BOTANY—The Registrar, The University, Sheffield (August 20).

LECTURER IN PHARMACEUTICS to teach to honours degree standard and to undertake research—The Staff Officer, The University of Aston in Birmingham, Gosta Green, Birmingham, quoting Ref. 490/6 (August 20).

SENIOR RESEARCH ASSISTANT (with a science or engineering degree) IN THE DEPARTMENT OF ENGINEERING SCIENCE, to carry out research in the field of thermodynamics in collaboration with Prof. Russell Hoyle—The Registrar and Secretary, University of Durham, Old Shire Hall, Durham (August 20).

RESEARCH OFFICERS or SENIOR RESEARCH OFFICERS (2), and a RESEARCH ASSISTANT IN THE COMPUTING CENTRE, to assist in computer programming arising from research in all departments of the University—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 21).

SENIOR TECHNICIAN (with experience in electronics) IN THE DEPARTMENT OF CHEMISTRY for assistance with research in electron spin resonance spectroscopy—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 22).

TEMPORARY ASSISTANT LECTURER (preferably with a special interest in political and moral philosophy) IN PHILOSOPHY—The Registrar, The University, Manchester, 13, quoting Ref. 180/66 (August 24).

ASSISTANT LECTURER or LECTURER IN PSYCHOLOGY—The Registrar, The University, Keele, Staffordshire (August 27).

EXPERIMENTAL OFFICER (with a degree or equivalent qualification in physics, chemistry, or in an appropriate technological subject, and experience in physical methods of analysis) IN THE ELECTRON PROBE AND X-RAY SECTION OF THE DEPARTMENT OF EARTH SCIENCES—The Secretary, Department of Earth Sciences, The University, Leeds, 2 (August 27)

LECTURER IN PHYSICAL OR INORGANIC CHEMISTRY—The Assistant Registrar (Science and Engineering), The University of Birmingham, Birmingham 14 (August 27).

RESEARCH ASSISTANT IN THE SOLID-STATE ELECTRONICS GROUP OF THE DEPARTMENT OF ELECTRICAL ENGINEERING AND ELECTRONICS for work on metal-semiconductor junctions, under the direction of Prof. E. H. Rhoderick—Prof. E. H. Rhoderick, Department of Engineering and Electronics, The University of Manchester Institute of Science and Technology, Manchester, 1 (August 30).

ASSISTANT LECTURER IN AERONAUTICAL ENGINEERING—Prof. A. V. Stephens, The Queen's University, Belfast, Northern Ireland (August 31).

LECTURER IN VETERINARY PARASITOLOGY IN THE SCHOOL OF TROPICAL MEDICINE—The Registrar, The University, Liverpool, quoting Ref. CV/187/N (August 31).

LECTURER or ASSISTANT LECTURER IN MICROBIOLOGY IN THE DEPARTMENT OF BOTANY—The Registrar, Queen Mary College (University of London), Mile End Road, London, E 1 (August 31).

RESEARCH ASSISTANT (with an honours degree in zoology and preferably a special interest in electron microscopy or nerve physiology) IN THE MARINE SCIENCE LABORATORIES, to work with Dr. D. A. Dorsett on the fine structure of invertebrate nervous systems—The Registrar, University College of North Wales, Bangor, North Wales (August 31).

RESEARCH OFFICER IN THE DEPARTMENT OF PHYSICS to investigate damage occurring in high-power laser systems—The Registrar, University of Essex, Wivenhoe Park, Colchester, Essex (August 31).

ASSISTANT LECTURER (with special qualifications and research interests in petrology, geochemistry or economic geology) IN THE DEPARTMENT OF GEOLOGY—The Registrar, The University, Nottingham (September 1).

JUNIOR LECTURER IN BACTERIOLOGY—The Secretary, Trinity College (University of Dublin), Dublin, Republic of Ireland (September 1)

LECTURER or ASSISTANT LECTURER (with an honours degree in engineering or mathematics and some experience in structural and/or machine vibration problems) IN THE INSTITUTE OF SOUND AND VIBRATION RESEARCH—The Deputy Secretary, The University, Southampton (September 1).

LECTURER or DEMONSTRATOR (with interests in the genetics and biochemistry of micro-organisms) IN THE DEPARTMENT OF GENETICS—Dr. Sydney Smith, Department of Zoology, The University, Downing Street, Cambridge (September 1).

LECTURER (with good academic qualifications and postgraduate experience, a special interest in the analysis and design of power generation and distribution systems, and familiarity with modern methods of analysis and simulation of systems, using computer techniques) IN ELECTRICAL ENGINEERING—The Registrar, University College of Swansea, Singleton Park, Swansea, South Wales (September 1)

RESEARCH SCIENTIST or SENIOR RESEARCH SCIENTIST (Physicist) (with a Ph.D. degree in physics or postgraduate experience of equivalent standard and duration, supported by satisfactory evidence of research ability) IN THE DIVISION OF APPLIED PHYSICS, Commonwealth Scientific and Industrial Research Organization, located at the National Standards Laboratory, University Grounds, Chippendale, Sydney, Australia, to undertake magnetic research—The Chief Scientific Liaison Officer, Australian Scientific Liaison Office, Africa House, Kingsway, London, W.C.2, quoting Appointment No. 750/364 (September 3).

UNITED STEEL COMPANIES FELLOW (engineering graduate) IN MECHANICAL ENGINEERING for research in the field of fluids or fluid power control—The Registrar, The University, Sheffield (September 3).

SCIENTIST (with a Ph.D. or honours degree, preferably with some additional experience in ruminant nutrition) AT RUAKURA AGRICULTURAL RESEARCH CENTRE, New Zealand, to assist in a research programme in dairy cattle nutrition aimed at evaluating pasture as a feedstuff for growing, lactating and fattening stock and at measuring the voluntary intakes of grazing stock, the factors which affect these and the feed requirements of grazing animals—The High Commissioner for New Zealand, New Zealand House, Haymarket, London, S.W.1, quoting Ref. B13/2/73/2823 (September 5).

POSTDOCTORAL FELLOW IN THE DEPARTMENT OF CHEMISTRY to work on new methods of peptide synthesis in collaboration with Dr. C. J. M. Stirling—Dr C. J M. Stirling, Department of Chemistry, King's College (University of London), Strand, London, W.C.2 (September 9).

LECTURER or SENIOR LECTURER (preferably specializing in bacterial or virus diseases of plants) IN PLANT PATHOLOGY IN THE DEPARTMENT OF AGRICULTURAL BIOLOGY, University of Ibadan, Nigeria—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 10).

SENIOR LECTURER (graduate in animal production, agriculture or science, with postgraduate specialization in any one of the major branches of animal production) IN ANIMAL PRODUCTION at the University of the West Indies, Trinidad—The Inter-University Council, 33 Bedford Place, London, W.C.1 (September 12).

LECTURER or ASSISTANT LECTURER (interested in any of the fields of animal physiology) IN PHYSIOLOGY—The Secretary, Royal Veterinary College (University of London), Royal College Street, London, N.W.1 (September 15).

LECTURER or SENIOR LECTURER (with special interests in physical chemistry) IN CHEMISTRY at the University of Tasmania, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, September 16).

LECTURER (with a special interest in and preferably some practical experience in electrical power engineering) IN THE DEPARTMENT OF ELECTRONIC AND ELECTRICAL ENGINEERING—The Registrar, The University, Sheffield (September 16).

SENIOR LECTURER IN PHYSICS, and a SENIOR LECTURER IN THEORETICAL PHYSICS at the University of Queensland, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S W 1 (London and Brisbane, September 16).

UNIVERSITY LECTURER (preferably with an interest in experimental taxonomy) IN BOTANY and Curator of the Claridge Druce Herbarium—The Administrator, Botany School, The University, South Parks Road, Oxford (September 20).

RESEARCH FELLOW IN THE SEDIMENTOLOGY RESEARCH LABORATORY OF THE GEOLOGY DEPARTMENT, to conduct an investigation into the sedimentology (including geochemistry, physical properties, and clay mineralogy) of facies variation in the Great Oolite Series of the Malmesbury area—The Registrar (Room 39, O.R.B.), The University, Reading (September 30).

SENIOR LECTURER IN PSYCHOLOGY at the University of Western Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 1).

ASSISTANT PLANT CYTOGENETICIST or ASSOCIATE PLANT CYTOGENETICIST (with an M S. or Ph.D. degree or equivalent, and training in plant cytogenetics) IN THE DEPARTMENT OF GENETICS—The Director, Agricultural Research Station, University of Puerto Rico, Rio Piedras, Puerto Rico (October 31).

CHAIR OF MICROBIOLOGY (Medical) at the University of Melbourne, Australia—The Association of Commonwealth Universities (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, October 31).

AGRICULTURAL OFFICER/STATISTICIAN, Scientific Officer Grade (with a degree in agriculture, botany or allied subject with a sound knowledge of statistics or a degree in statistics with an interest in agriculture) for duties which will be concerned with the planning and analysis of scientific investigations undertaken by the Board—The Establishment Officer, Potato Marketing Board, 50 Hans Crescent, Knightsbridge, London, S.W.1.

ASSISTANT EXPERIMENTAL OFFICER/EXPERIMENTAL OFFICER (with an interest in biophysics) to be responsible for the operation and development of techniques using the analytical ultracentrifuge—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 66 12.

BASIC GRADE BIOCHEMIST (university graduate in biochemistry or chemistry or A R.I.C.) IN THE DEPARTMENT OF CHEMICAL PATHOLOGY for duties which will include routine steroid assays—The Clerk to the Governors, St. Bartholomew's Hospital, London, E.C 1, quoting Ref. No. ASC/112.

BIOCHEMICAL RESEARCH ASSISTANT to work on effects of stress in rats—Dr. G Curzon, Institute of Neurology, The National Hospital, Queen Square, London, W C 1.

BIOCHEMIST (Basic Grade, probationary or post-probationary) IN THE ASSISTED VENTILATION UNIT, for duties concerned primarily with blood gas analysis and biochemical aspects of investigation into metabolic disturbances, associated with respiratory failure—The Personnel Officer, Royal Infirmary, Edinburgh, 3

EDITORIAL ASSISTANT (with a degree in science and preferably some editorial experience) for the *Biochemical Journal*—The Editorial Board, The *Biochemical Journal*, 20 Park Crescent, London, W.1.

EXPERIMENTAL ECOLOGIST or LIMNOLOGIST IN THE DEPARTMENT OF BOTANY—Prof. N. P. Badenhuizen, Department of Botany, University of Toronto, Toronto 6, Ontario, Canada.

EXPERIMENTAL OFFICER (with a sound working knowledge of chemistry and experience of several instrumental methods) IN THE DEPARTMENT OF CHEMISTRY for work concerned with the development and application of instrumental analytical techniques and methods of relevance to chemical industry and new processes—The Registrar, The University of Manchester Institute of Science and Technology, Sackville Street, Manchester, 1, marking envelope "Experimental Officer—Analytical".

HISTOLOGIST (with an honours degree in physiology or zoology or an equivalent qualification and preferably previous experience of histological techniques) IN THE PHYSIOLOGY DEPARTMENT to be in charge of the histological work of the Department and to collaborate in research, mainly in the field of endocrinology—The Secretary, National Institute for Research in Dairying (University of Reading), Shinfield, Reading, Berkshire, quoting Ref. 21/N/66.

HISTOLOGY TECHNICIAN (preferably with at least one year's experience in histology and with I.M L.T. or appropriate G C E. "A" level qualifications) IN THE DEPARTMENT OF EXPERIMENTAL PATHOLOGY, Chester Beatty Research Institute, Fulham Road, London, S W.3—The Secretary, Institute for Cancer Research, Royal Cancer Hospital, 34 Sumner Place, London, S W.7, quoting Ref. 301/B/240.

PHYSICIST required for one year to develop some diagnostic uses of radioactive isotopes including scanning—The Secretary, St. Mary's Hospital Medical School, London, W 2.

RESEARCH ASSISTANT (with a degree or higher degree in aeronautical, civil or mechanical engineering, or physics, with some research experience) IN THE DEPARTMENT OF AERONAUTICS, to engage in fundamental research connected with the forces on buildings and structures due to atmospheric wind—Prof. P. R. Owen, Department of Aeronautics, Imperial College of Science and Technology, London, S.W.7.

RESEARCH FELLOW (with postdoctoral research experience and interested in the possibility of a permanent University appointment) IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY to assist Prof. K. A. Munday in an investigation into the effect of osmotic changes on biochemical properties of subcellular particles of invertebrates—The Deputy Secretary, The University, Southampton.

SENIOR TECHNICIAN or TECHNICIAN IN THE DEPARTMENT OF MEDICINE to be responsible for technical work for a research programme investigating the chemical control of respiration—Prof. W. I. Cranston, St. Thomas's Hospital Medical School, London, S.E.1.

TECHNICAL OFFICER (with a knowledge of electronics) IN THE DEPARTMENT OF GEODESY AND GEOPHYSICS to help with the design, construction and

maintenance of new instruments for research and to take part in short expeditions abroad on land and sea—Secretary of the Faculty Board, c/o Department of Geophysics, University of Cambridge, Madingley Rise, Madingley Road, Cambridge.

TECHNICIAN (experienced in histological techniques) as personal assistant on a research project in the DEPARTMENT OF ZOOLOGY (the work will involve tissue culture and histology)—The Registrar, The University, Liverpool 3, quoting Ref. 154/N.

THE NUMBERS GAME

It takes courage to go among physicists and suggest that the United Kingdom may be spending too much on nuclear physics. That is the first thing to be said about the Presidential Address by Sir Gordon Sutherland (see p. 792) to the Institute of Physics and the Physical Society (which should long ago have found a less cumbersome description for itself). It is also courageous to stand up in public and consider how and when to call a halt to the steady growth of spending, in the past two decades, on research and development. Lord Bowden did a lot to set this ball rolling during his stay at the Department of Education and Science. The Council for Scientific Policy, in its last report, took the process an important stage further by publicizing its preoccupation with the problems of balancing the limitless opportunities which exist for spending money against the understandable wish of the British Treasury that the pace of growth should be reduced. Obviously the council will find itself exposed to even greater pressures in the months ahead, and if it is to know when to yield gracefully and when to dig in its heels, it will have to be provided with a rational philosophy for deciding what should be spent on research and development. If what Sir Gordon has been saying should stimulate a search for the objective yardsticks which circumstances demand, much will have been accomplished.

But what yardsticks should there be? This is where the fun begins. One difficulty is that there is bound to be confusion between the questions of how to allocate resources between different branches of science and how to determine what proportion of a nation's entire wealth should be spent on science as a whole. Another is that there is no simple univalent rule for calculating how much to spend on research and development but, rather, an untidy jumble of incommensurable arguments, some of them in conflict with each other. Often it is only possible to establish lower limits to the amounts of money that should be spent on science and technology. Certainly the familiar yardstick which consists of the fraction of the Gross National Product spent on research and development is only the crudest rule of thumb. By making it the central pillar of his argument to the physicists, Sir Gordon Sutherland may have oversimplified the issues and—in the process—may have given comfort to the British Treasury.

There is no natural law to decree what proportion of a nation's wealth should be spent on science and technology. The fact that the United States and the United Kingdom spend roughly the same is not in itself an assurance that these are the proportions that sensible nations ought to spend. Everything depends on the goals they set themselves, and on the speed with which they seek to attain them. In any event, in the comparison between Britain and the United States, the absolute amounts of effort being spent may be more significant than the corresponding proportions of the G.N.P. Except in space research, where Britain has been mercifully modest, the smaller nation has not openly limited its ambition in science and technology. Should it not therefore spend on research and development an amount comparable to what is spent in the United States? In other words, should not the United Kingdom be spending 10 per cent of its G.N.P. on research and development? Certainly if it chooses to spend a mere 2·7 per cent, it should more openly acknowledge that this is only a poor man's pittance, and that a great many of the things which are done well in the United States cannot be done at all in Britain.

The comfortable arithmetic based on fractions of the G.N.P. conceals the sad truth that in British research and development, resources are spread too thinly, and that the most immediate need is to find some way of concentrating on a manageable portfolio of ambitions. On the long view, it may be necessary for smaller nations to acknowledge that the only way of keeping up with the Joneses is to spend a disproportionately large proportion of their wealth on scientific research and development. The time may come when really well-off nations spend their wealth on leisure—golf and foreign travel—while their less successful imitators have to keep on slaving away in the laboratories. In other words, there is no particular reason why the spending on science in Britain should now level off a respectful interval below the plateau (as a fraction of the G.N.P.) which seems to have been attained in the United States. Another way of putting this is to suggest that if spending on research and development is linked to anything, it is to the expected growth of the G.N.P. and not to its absolute amount.

In Britain, there are other reasons for believing that the growth in expenditure on research and development should continue for some time yet. For one thing, those engaged on research and development are not always fully provided with the resources which make for effective work. Not all laboratories are as well equipped as the National Physical Laboratory. Possibly there are similar problems in the United States, and statistics recently compiled by the OECD suggest that in 1962 the average spending for each qualified scientist engaged on research and development amounted to $40,000, compared with $30,000 in the United Kingdom. The difference is scarcely enough to account for the differences in rates of pay. Yet in both countries it is essential that the fullest use should be made of the limited stock of skilled manpower. In both places there is probably room for more growth in spending simply so that people now at work shall be effectively employed.

In Britain there is a specific reason why growth should continue for some years to come. The universities and similar institutions are at present turning out more than 20,000 qualified scientists each year, and it must be hoped that at least a quarter of these will find their way into research and development. Indeed, for some years to come, the annual increase of the labour force in research and development must be expected to grow by 7 or 8 per cent a year if the fullest value is to be derived from the expansion which the universities have been asked to undertake. In other words, the annual cost of research and development should be expected to increase by some £60 million even without the inflationary pressure of the steadily increasing cost of research and development of all kinds. Even if, as now seems likely, the G.N.P. does not change very much for some years to come, it would be folly to fail to make full use of the skilled manpower which has been expensively trained in recent years. There are ways of finding lower limits to what should be spent on research and development—of suggesting how governments should make proper use of resources which exist already, or which will exist in the years immediately ahead. But what of the more distant future? How many qualified scientists and engineers will Britain need in the eighties? How much will have to be spent each year if each is to work effectively? There are no ready answers to questions like these, yet there is no sign that the trend towards increasing dependence on science and technology which has been the history of the past three decades will now quickly come to a halt. Indeed, things point mostly in the other direction. It will be a great surprise if the proportion of the G.N.P. being spent on research and development comes suddenly to a halt, in Britain or in the United States, in 1966. In the months between now and Christmas, when British government departments will be trying to decide how money should be spent in 1967–68, the Council for Scientific Policy will be saddled with the task of persuading the Treasury that growth is probably inescapable. The job would be far easier if the available statistics were more reliable. It will be impossible if there is too much dependence on fractions of the G.N.P.

MALE AND FEMALE

IT is naturally disappointing to read, on page 863 of this issue, that an interesting attempt to pre-determine the sex of cattle has not so far been successful. For some years now, work has been under way at the Institute of Animal Physiology of the Agricultural Research Council, and British farmers (as well as British newspapers) have been awaiting its outcome with the greatest interest. They should not now be too downcast, for success at this stage may have been almost too much to hope for.

Dr. Keynes and his colleagues at Babraham have been following a lead provided by Dr. B. C. Bhattacharya several years ago, in some experiments with rabbits. Then it seemed that if rabbit semen were cooled to 1° C to bring to a halt the movement of individual sperms, two distinct fractions would separate under the influence of gravity, that tending to sink more quickly tending to contain a predominance of sperms carrying the *X* chromosomes which determine female offspring. The less dense fraction of the semen, on the other hand, would tend to contain a majority of *Y* chromosomes and would, to that extent, produce buck rabbits when inseminated into fertile females. By all accounts it is extremely difficult to ensure that separation under gravity is not disturbed, which may be one explanation for the negative result of the experiment with cows at Babraham. But it may also be that such differences as exist between the sperms which carry *X* and *Y* chromosomes may not be significant in semen from bulls but just enough to make a perceptible difference in rabbits. More may be known about this when there has been a chance to improve on the statistical validity of the work with rabbits. In any event, however, progress is bound to be unsure until much more is known about the mechanism by which the supposed separation of sperms under gravity can be accomplished. The fact that *X* chromosomes are larger and therefore heavier than *Y* chromosomes is not a sufficient explanation, for the difference of density that would result is insufficient to explain the segregation which is observed. But may there not be physiological differences between sperms of the two kinds? This is what needs most urgently to be determined. Until much more is known about the ways, if any, in which the sex chromosomes can influence the macroscopic behaviour of the sperms which carry them, those who attempt to segregate fractions of semen will necessarily be working in the dark.

It does not follow, of course, that there can be no hope of determining the sex of cattle until all the more fundamental research has been successfully carried out. On the contrary, there is such a great economic benefit to be won from a way of making sure that dairy herds do not waste nearly half their breeding potential on unwanted bull calves that experiments are bound to continue, and deserve to be supported generously. But there are also other lines of enquiry to be followed. Talk of implanting fertilized ova of determined sex in fertile females is not entirely fanciful, even if there can be no assurance that methods which work with difficulty in the laboratory, and with laboratory animals, can be adapted to the trying circumstances of agriculture where, for example, surgical techniques are out of the question. Even if further developments should show that it is unreasonable to look for success, the comparatively modest cost of the work which needs doing would be an entirely prudent gamble. And fortunately there is no immediate prospect that it will be possible to apply any of these techniques to human beings, though it may not be too soon to ask how society should adapt itself to such a possibility.

NEWS AND VIEWS

Tribology for Some

THE Minister of Technology, Mr Anthony Wedgwood Benn, has now announced the formation of what is to be known as the Committee on Tribology. This is the first sign, so far, of the attitude of the British Government to the report of a working party under Mr. Peter Jost which appeared under the imprint of the Department of Education and Science earlier this year. The committee, soon to be established, is said by the Minister of Technology to be a means of deciding "how the objectives of the report can be most effectively pursued". It is not, therefore, to be confused with the committee whose formation was recommended in the report of the working party, and whose function was supposed to be the co-ordination of research and the provision of a forum for the exchange of information. According to Mr. Benn, one of the first questions to be asked of the new committee is whether the encouragement of better lubrication practices in British industry is really dependent on the development of what the report called "Institutes of Tribology".

Since the publication of the report, the Institutes of Tribology have become the acid test which separates the tribologists from the non-believers. The original working party wanted to see the creation of "several national centres in lubrication engineering to become Institutes of Tribology". The institutes were to undertake research in tribology, provide opportunities for post-graduate education and "form and maintain a two-way bridge with industry", partly by attracting industrial men and women to research and teaching in tribology, and partly by providing "a specialist tribological service to industry on an *ad hoc* as well as a regular basis" Institutes were to be placed near academic institutions for the sake of the education, and near industrial centres so as to function effectively as consultants.

This proposal has fallen foul of critics for several different reasons. Some, this journal among them (*Nature*, **210**, 338; 1966), have argued that the proposals are needlessly grandiose. Others have opposed them because they seem to cut across the legitimate interests of established institutions, and in particular because they would be certain to duplicate work that is being done, or which should be done, by existing organizations for industrial research. The Department of Education and Science has remained somewhat unenthusiastic about the proposals in the report, though there is said to have been a welcome for them by some members of the University Grants Committee. The Ministry of Technology has been hesitant, although there is reason to believe that an announcement on tribology was at one stage to have been made by the previous Minister of Technology, Mr. Frank Cousins, on the eve of his resignation from that post. From this point of view, the decision to create a new committee should be a welcome opportunity to resolve the differences between the tribologists and their critics. If the outcome should be a demonstration of how engineering departments in universities can more effectively help industry to some of the benefits, often exaggerated, of better tribology, nobody will complain. If the result is merely a better understanding of what the working party on tribology was really getting at, even that will be something gained.

ELDO under Scrutiny

THE view that the European Launcher Development Organization (ELDO) has not, so far, been "value for money" for the British Government has been made public by a sub-committee of the Estimates Committee of the House of Commons (*Second Report from the Estimates Committee*, 1966–67, *The European Space Launcher Development Organization*, H.M.S.O., 19*s*.). The report stands out among such documents for its topicality; it carries the history of the negotiations between the British Government and its European partners up to the meeting in Paris on July 7 at which a re-allocation of the costs of ELDO among the participants was finally agreed. Some of the verbatim evidence in the report is no older than a month.

For all the reputation of the Estimates Committee as a counter of candle ends, the enquiry on ELDO seems to have been concerned as much with the future as the past. It is made clear, however—possibly for the first time—that the French proposal at the beginning of 1965 for the virtual replacement of the original ELDO programme by a much more ambitious venture was, at the time, as much of a shock as the circulation by the British Government of a memorandum expressing serious doubts about ELDO in February 1966 and its public declaration to that effect at the beginning of June. The sub-committee, by its questioning of officials from the Foreign Office, did very little to define for public purposes how the Government's doubts could have been resolved by the decision that the scale of its contribution to future costs should be 27 per cent and not 38 per cent, although it is also now written into the agreements on ELDO that future increases of cost will not automatically be passed on to unconsenting partners.

On the value of the ELDO programme, the committee was concerned to establish that the present ELDO PAS programme will yield by 1970 a launching vehicle capable of putting into a geostationary orbit satellites of 150 kg or so, which will carry some 2,500 voice channels of communication. It was common ground among the witnesses that such satellites will not be capable of direct television broadcasting, but there was disagreement about the extent to which they would be able to form part of a world-wide satellite network by the early seventies. ELDO was supported with scant enthusiasm by the representatives of the British Post Office, who held firmly to the view that the United Kingdom could secure her interests in the future of telecommunications by negotiations within the international organizations for the time being responsible for the development of the satellite network. The same exchanges disclosed that British companies had been invited to tender for the six satellites now being developed for INTELSTAT, and had not felt able to put in a bid.

The sub-committee's general conclusion is that the decisions just reached on ELDO "are not a solution to the real problem", and that there is a need immediately to take decisions about the long-term future of the organization, with adequate guarantees of long-term finance. It promises that it will soon turn its attention to the general question of space research in Britain, and its present report is heavy with hints

of how France has arranged that there should be a national space programme in parallel with ELDO. This prospect of continuity has prompted some suggestions that the sub-committee may emerge as a British equivalent of the congressional committees in the United States, but it is only proper to point out that the minutes of evidence now published show that it has a long way to go to earn this title. Vital pieces of evidence remain unpublished. The pursuit of truth is often impeded by gentility. Holding these enquiries in public would help to give them point. The lack of full-time secretariat plainly shows.

More Power for *Dragon*

AT least one dragon is trying to avoid obsolescence. The *Dragon* Project of the European Nuclear Energy Agency is moving rapidly ahead with designs for what is hoped will be a competitive 1,250 MW (thermal) power reactor plant generating 540 MW of electricity. The seventh annual report of the Project for the period from April 1, 1965, to March 31, 1966, reviews the advances that have been made, especially since the high temperature gas cooled reactor at Winfrith Heath, Dorset, was completed and its full design output was achieved. The results have been so encouraging that, despite the competition of other operative reactor designs such as the United Kingdom's fast breeder reactors, a further £1·5 million has been allocated to extend the agreement from April, 1967, to the end of that year. There remains the possibility of another extension to March, 1970.

The *Dragon* project was set up in 1959 under an agreement concluded between 12 member countries of the European Nuclear Energy Agency, six of which belong to the Euratom Commission; the original agreement was for five years, but in 1962 this was extended to eight years with an increase in the budget from £13·6 million to £25 million. An agreement in 1964 on collaboration with the United States Atomic Energy Commission provided for the exchange of information and documents and reciprocal visits by scientists. A similar agreement was concluded in July, 1965, with the Thorium High Temperature Reactor Association at Julich, Germany, and permits joint use of the *Dragon*'s major research facilities.

What to Buy?

THE perennial question of how a library should spend its money on scientific journals may be a little easier to answer after the Center for Research Libraries at Chicago has finished the programme of research which it has persuaded the National Science Foundation to finance. The intention is to help libraries to decide whether it is better to subscribe to a journal or, alternatively, to borrow from another library or to buy photo-copies of those items in journals when—and only when—they are needed. If speed of access is the prime consideration, there may be no substitute for acquisition and storage on the spot, although the centre points out that libraries may often be able to provide a better service for the same cost if they acquire several copies of frequently used journals and rely on borrowing the others. With journals the contents of which fade rapidly into limbo, it may be more economical to buy but not to bind. Sometimes it will be best for libraries to borrow all but a few serial publications.

Librarians and the academic committees which advise them are familiar enough with these alternatives. The Center for Research Libraries hopes to be able to help by making a detailed analysis of the use of serial journals, and of the costs to libraries of the various stages in handling them. The first product of the research programme will be a set of mathematical formulae by means of which librarians can hope to decide objectively how best to use their budgets. But there should also be a wealth of information to augment the present scanty knowledge of what really happens to the individual copies of the journals after they reach the shelves of libraries. The Center for Research Libraries has obviously done something to win the heart of the National Science Foundation by pointing out that some scientific papers which appear in journals are read by no more than twenty-five people. Much, of course, depends on the meaning of the verb *to read*.

Healthy Seeds

DR. JOHN GRAINGER writes: The International Seed Testing Association has begun to publish Series 3 of its *Handbook on Seed Health Testing* (Secretariat of the Association, Bennenhaven 1, Wageningen, The Netherlands; working sheets 1–33, except No. 15 and No. 23, $1.00 plus $1.00 for special cover). This is a loose-leaf folder of thirty-one sheets, each of which gives directions for methods of revealing the presence of particular seed-borne pathogens. It is introduced and largely compiled by Dr. Mary Noble of the Department of Agriculture and Fisheries for Scotland, East Graigs, Edinburgh, but individual sheets have been prepared by Dr. Rohloff of Germany, Dr. Meiri of Israel and Dr. Wallen of Canada. The present series deals with oat (three pathogens), *Brassica* seeds (four pathogens), carrot (two), soya bean (one), barley (five), lettuce (one), flax (one), rice (seven), opium poppy (one), pea (one), sesame (one), wheat (three) and *Zinnia elegans* (one pathogen). This list alone shows the international scope of the project. Methods used for examination are mainly incubation on or between blotters or in a rolled paper towel, sowing in brickstone or sand, or the placing of seeds on an agar plate. These simple, successful methods are, however, made precise by the specification of standard conditions such as depth of sowing, length of incubation at a particular temperature, and sometimes the character and diurnal variation of illumination.

Particular interest attaches to a method of revealing seed-borne lettuce mosaic virus by culture in controlled environment—a standard peat medium at a temperature of 10° C for 3–5 days in the dark, then 13–19 days at 25°–27° C in continuous illumination by warm-white fluorescent tubes. Mosaic symptoms appear on the first three true leaves of the lettuce if the disease is indeed carried by the seed. Washing the seed sample may reveal the presence of some pathogens, while the herbicide, 2 : 4-dichlorophenoxyacetic acid (2 : 4-D), is occasionally necessary to prevent germination when, for example, cabbage seeds are examined for *Sclerotinia* rot. Loose smut of barley can only be revealed by the microscopic examination of embryos. Each sheet is clearly illustrated by excellent half-tone blocks and line drawings of the pathogen as revealed by the methods considered. In this the present volume is

complementary to another part of the Handbook (Series 4 (1)) by Malone and Muskett, which described seventy-seven species of seed-borne fungi for purposes of recognition. Since the publication of Series 3, I have received 'working' copies of eleven further working sheets, an earnest that this most important international section of agricultural science is being expanded energetically.

Liquid Inorganic Laser

A LIQUID laser radiating at 1·06 microns and based on a solution of neodymium oxide in selenium oxychloride has been developed by Dr. Adam Heller and Dr. Alexander Lempicki, of General Electric and Telephone Laboratories Inc., according to the current issue of *Applied Physics Letters*. The device is a successor to an earlier laser based on a solution of a rare-earth in an organic chelating compound, the efficiency of which was limited by energy absorption by light atoms in the solvent. The working characteristics of the selenium oxychloride laser have not yet been determined, but pulses of 1 joule have so far been obtained with an input of energy measured as some hundreds of joules.

Long Range Weather

THE Meteorological Office is cheerful if restrained about the success of its long range weather prediction service in its annual report for 1965—the year that saw Professor B. J. Mason succeed Sir Graham Sutton as director-general (*Annual Report on the Meteorological Office*, H.M.S.O., 9*s*.). Long range forecasts for a period of thirty days ahead have been published twice a month for the past three years. On the basis of the first two years of the service, the Meteorological Office says that results have been slightly better than originally expected. According to the annual report for 1965, forecasts are assessed after the event by a panel of meteorologists, and "marks are given for the accuracy of forecasts of temperature, rainfall and additional information". Predicting temperature seems to be the easiest, with twenty-eight out of fifty forecasts ranking for the mark "good agreement". On rainfall, however, agreement between forecasts and reality was good on fourteen occasions, moderate on seventeen and deserving the description "little agreement" on nineteen occasions.

The long range forecasts are based on searches of records going back to the middle of the nineteenth century for analogous patterns of mean temperature and mean pressure in the northern hemisphere, and of successions of daily weather patterns in the British Isles. To predict for September 1966, for example, a search is made for weather patterns in August in earlier years which resemble that of August 1966. The long range weather forecasters are cheerful if they can find several years in which very similar August patterns are followed by September patterns which also resemble each other, and they then predict with confidence (though not necessarily with success) that September 1966 will be much the same as the earlier Septembers. Evidently this happy set of circumstances is not often repeated, however, and the report also points out that much will have to be done before the parameters which are really significant in this technique of analogous forecasting can be identified.

What might be called objective long range forecasting is reckoned to be an extremely distant prospect. Routine forecasts produced by computers have been available for nearly a year, and are said to be already as good as those produced by experienced forecasters. According to the report, the possibility of producing reliable computed forecasts for five days ahead is being seriously considered in the United States, and is also the motive for the proposed programme of World Weather Watch now being considered by the appropriate international organizations, and in which the Meteorological Office thinks it may be asked to play an important part.

Academics make Maps

DESPITE the fact that many European geological surveys rely largely on university personnel for their routine geological mapping, the sentinels of British geological surveying have long argued against such an arrangement. They have claimed that the system does not lead to the building up within the organization of the stock of experience and knowledge which the staff of a good survey needs. Moreover, they are at pains to point out that the survey man is a very different specimen from the academic geologist. Although the latter tends to follow his fancies and become a specialist, the professional surveyor must give—and be seen to give—his wholehearted and impartial attention to all facets of the geology which he encounters. In the past the Geological Survey of Great Britain has suffered somewhat from an inborn fear that a taste of academic bliss could entice away members of its staff.

Recently, with the advent of new geophysical and geochemical methods of surveying—most of which incur organization and finance beyond the reaches of many university departments—the boot has moved gradually over to the other foot. The Survey has become less churlish about entering into co-operative schemes with universities. The most recent contract to go to a university—and the first to deal with the production of a one inch geological map—speaks much for Sir James Stubblefield's efforts during his directorship of the Survey to foster relationships with universities. Through Prof. Scott Simpson's persuasiveness, the Department of Geology in the University of Exeter has received a contract from the Natural Environment Research Council on behalf of the Survey (now incorporated in the Institute of Geological Sciences). Over a period of 5 years, six postgraduate students will work under the joint supervision of the University of Exeter and the Geological Survey to re-survey the region covered by *G.S.E.W. One Inch Sheet* 339 (*Teignmouth*). This particular sheet was chosen because of the need to revise the Devonian and Carboniferous stratigraphy and structure of South Devon in the light of recent advances in the stratigraphy of South-West England, and because it is believed that the re-investigation of the Bovey Beds and the Haldon gravels will yield useful results. Although some of the ground has been re-surveyed on a scale of six inches to the mile, and although there were airborne surveys in the mid-fifties, the map itself has not been revised since 1909.

Sir James Stubblefield has made it clear that the Geological Survey would be prepared to consider approaches from other university departments with the view of further joint projects.

Parliament in Britain

THE Minister of Technology, Mr. Wedgwood Benn, announced in the House of Commons on August 9 that the first Institute for Advanced Studies of Design will soon be established on the site of the National Engineering Laboratory at East Kilbride, Scotland. Mr. Benn was replying to a question on plans for implementing the recommendation of the Fielden Committee to establish such institutes. He said that the first institute would be devoted to advanced machine and control technology and that a director will soon be appointed who will also be a full member of the University of Strathclyde. The Establishment will be under the Ministry of Technology, but the Steering Committee will represent industries, trade unions and the university.

ROUGHLY 55 per cent of the domestic computer business is conducted on rental, according to Mr. Anthony Wedgwood Benn in a written reply to a question about the renting of industrial machinery on August 12. He said that the ministry has no information about the extent of renting for other types of machinery, but that he is hoping that the new arrangements for investment grants will lead to "more flexible leasing terms" for new types of machinery.

RECRUITMENT of staff for the National Reference Library for Science and Invention was said by Mr. Goronwy Roberts, Minister of State at the Department of Education and Science, to be well under way. His written reply to a question on August 11 was that thirty-eight librarians and others had been recruited since the beginning of the year, although only sixteen of these would fill new posts. As yet it appears that the part of the National Lending Library housed at the British Museum is not open to the public, but that what remains in the old Patent Office Library is still accessible.

THE National Foundry College is no longer receiving government assistance because it is "a small monotechnic". The subject was raised in the House of Commons on August 12, and in a written reply Mr. Goronwy Roberts stated that the decision was based on the extensive development of the provision by local education authorities for higher technological education since the college was set up in 1948. In the future a more broadly based institution within the local authority sector will be better able to meet the needs of the foundry and other industries.

FOLLOWING the recommendations of the Geddes Report on the shipbuilding industry, a Shipbuilding Industry Board will be set up under the chairmanship of Mr. William Swallow, until recently chairman and managing director of Vauxhall Motors, Ltd. The board's task is to promote the reorganization of the industry, principally by holding discussions with firms and unions in advance of legislation. This announcement was made by Mr. Douglas Jay, President of the Board of Trade, in a statement to the House of Commons on August 9. He added that implementation of the productivity bargains will be deferred for six months, in accordance with the White Paper, but that both the Government and the Industrial Re-organization Corporation were prepared to give financial assistance if required.

University News: London

PROF. J. BROWN, at present professor of electrical engineering at University College, has been appointed to the chair of light electrical engineering tenable at the Imperial College of Science and Technology. Mr. L. Castillejo, at present lecturer in theoretical physics and fellow of Wadham College, has been appointed to the second chair of physics tenable at University College. The title of professor has been conferred on the following: Dr. R. A. Kekwick (biophysics, in respect of his post at the Lister Institute of Preventive Medicine); Dr. S. J. Pirt (microbiology, in respect of his post at Queen Elizabeth College); Dr. J. C. Sloper (experimental pathology, in respect of his post at Charing Cross Hospital Medical School); Dr. R. E. B. Hudson (pathology, in respect of his post at the Institute of Cardiology).

Southampton

MR. H. CHARNOCK, at present principal scientific officer in the National Institute of Oceanography, has been appointed to the chair of physical oceanography.

Appointments

DR. R. S. F. HENNESSEY, at present head of the Therapeutic Research Division of the Wellcome Foundation Ltd., has been appointed assistant research director with responsibility for scientific administration. Prof. M. Weatherall, at present professor of pharmacology at the London Hospital Medical College, has been appointed head of the Therapeutic Research Division of the Wellcome Research Laboratories.

DR. B. R. NIJHAWAN, director of the National Metallurgical Laboratory, Jamshedpur, has been appointed to the United Nations Organization as senior adviser (Inter-Regional), Centre for Industrial Development (Technological Division) in New York.

Announcements

THE American Society of Plant Physiologists has chosen Prof. Daniel I. Arnon, of the University of California (Berkeley), as the recipient of its Stephen Hales Award; Prof. Kenneth Thimann, of the University of California (Santa Cruz), for the Barnes Life Membership Award; and Prof. C. B. van Niel, of California, for the Kettering Award. At the annual meeting of the Society held at the University of Maryland recently, Prof. R. S. Bandurski, of Michigan State University, was elected president.

A NATIONAL Medal of Science has been established in the United States to recognize individuals who have made outstanding contributions in the physical, biological, mathematical and engineering sciences, and the first awards have been made to: PROF. R. H. BING, professor of mathematics in the University of Wisconsin; PROF. M. CALVIN, professor of chemistry in the University of California; PROF. H. E. CARTER, professor and head of the Department of Chemistry and Chemical Engineering in the University of Illinois; DR. P. CHENEA, vice president for academic affairs in Purdue University; PROF. B. L. CRAWFORD, JUN., professor and chairman of the Department of Chemistry in the University of Minnesota; DR. J. C. FLETCHER, president, University of Utah; DR. H. J. HOLLOMON, assistant secretary of commerce for science and technology; PROF. P. J. KRAMER, professor of botany in Duke University; PROF. G. LINDZEY, professor and chairman of the Department of Psychology in the University of Texas; PROF. W. MCDERMOTT, professor of medicine in Cornell University; DR. R. REVELLE, director of the Harvard Center for Population Studies in Harvard University; DR. A. M. WEINBERG, director of Oak Ridge National Laboratory.

A COURSE of instruction in powder technology leading to a master of science degree or to the college postgraduate

diploma will commence at King's College London in October. The course will last for one year, and is designed for students who have a first degree in engineering, physics, chemistry, or certain other approved branches of applied science. Further information can be obtained from Mr. A. Davies, King's College London, Strand, London, W.C.2.

A DISCUSSION group for users of gel permeation chromatography will be held at Shell Centre, London, on September 13. Further information can be obtained from A. Lambert, Shell Research Limited, Carrington Plastics Laboratory, Urmston, Manchester.

AN international conference on "Forensic Activation Analysis" will be held in San Diego during September 19–21. Further information can be obtained from Dr. V. P. Guinn, General Atomic, P.O. Box 608, San Diego, California.

A CONFERENCE on "The Physical Basis of Yield and Fracture", arranged by the Stress Analysis Group of the Institute of Physics and the Physical Society, will be held in the University of Oxford during September 28–30. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A CONFERENCE on "Nuclear and Particle Physics", arranged by the Nuclear Physics Sub-Committee of the Institute of Physics and the Physical Society, will be held in the University of Glasgow during September 21–23. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A CONFERENCE on "The Physics of Semiconducting Compounds", arranged by the Institute of Physics and the Physical Society, will be held at the University College of Swansea during September 21–23. Further information can be obtained from the Meetings Officer, the Institute of Physics and the Physical Society, 47 Belgrave Square, London, S.W.1.

A SYMPOSIUM on "Plastics and Polymer Technology" will be held at the Borough Polytechnic, London, during October 27–28. Further information can be obtained from the Secretary, Borough Polytechnic, Borough Road, London, S.E.1.

A SYMPOSIUM on "Solid State and Chemical Radiation Dosimetry in Medicine and Biology" will be held, under the auspices of the International Atomic Energy Agency, in Vienna during October 3–7. Further information can be obtained from the appropriate national authorities responsible for atomic energy matters.

A SYMPOSIUM on "Combustion in Advanced Gas Turbine Systems" will be held at the College of Aeronautics during April 4–6, 1967. Papers are being sought for the symposium and any correspondence should be sent to Dr. I. E. Smith, The College of Aeronautics, Cranfield, Bedford.

A SYMPOSIUM on "Microwave Measurement", organized by the Scientific Society for Measurement and Automation, member organization of IMEKO in Hungary, will be held in Budapest during October 12–14. Further information can be obtained from the Organizing Committee of the IMEKO—Symposium on Microwave Measurement, P.O.E. 457, Budapest 5.

THE third symposium on "Flames and Industry", arranged jointly by the Institute of Fuel and the British Flame Research Committee, will be held at the Imperial College of Science and Technology, and the Royal Institute of British Architects, during October 18–19. Further information can be obtained from the Secretary of the Institute of Fuel, 13 Devonshire Street, Portland Place, London, W.1.

A SYMPOSIUM on "Physico-chemical and Biophysical Factors affecting the Activity of Pesticides", under the auspices of the Pesticides Group of the Society of Chemical Industry, will be held at the London School of Pharmacy during April 11–12, 1967. Further information can be obtained from Dr. M. B. Green, Imperial Chemical Industries, Ltd., Mond Division, P.O. Box 8, The Heath, Runcorn, Cheshire.

A SYMPOSIUM on "Spectroscopy of Macromolecules" is part of the programme of the thirteenth Colloquium Spectroscopicum Internationale, sponsored by the Canadian Association for Applied Spectroscopy and the Society for Applied Spectroscopy, to be held at Carleton University during June 19–23, 1967. Further information can be obtained from Mr. A. W. Pross, Central Research Laboratory, McMasterville, Quebec.

A SYMPOSIUM on "Ceramic Materials and their Properties", sponsored by the American Ceramics Society, the National Bureau of Standards, and the American Society for Testing and Materials, will be held at the National Bureau of Standards in Gaithersburg, Maryland, on October 14. Further information can be obtained from Dr. Wachtman, National Bureau of Standards, Washington, D.C.

HOW TO SPEND MONEY?

The following are extracts from the Presidential Address to the Institute of Physics and the Physical Society, entitled "Rate of Growth of Expenditure on Science", delivered on May 3, 1966, by Sir Gordon Sutherland, Master of Emmanuel College, Cambridge.

THE expenditure of the research councils has grown over the past 25 years as shown by the figures in Table 1 (taken largely from the report of the Advisory Council for Scientific Policy for 1963/64). In 1938/39 the total expenditure of the research councils was £1.43 million. By 1964/65 this had grown to nearly £50 million. The overall compound annual per cent increase is 14·6 over the 26 years. It is on the basis of these figures that the statement is often made that Britain has been doubling her expenditure on science every 5 years.

The expenditure of the universities on research in science and technology shows a similar trend, although the period for which reasonably accurate figures are available is much shorter. The figures are given in Table 2. Here we find that expenditure has risen from £20 million in 1958/59 to more than £50 million in 1964/65. If we divide this interval into two periods of 3 years, then the compound annual per cent increase increased from 13·3 for the first three years to 19·1 for the last three. Thus in the research councils and the universities the annual expenditure is not only rising but the rate at which it is rising is also increasing. It is this increase in the rate of increase which is rightly beginning to cause concern. If these trends were to continue for even 10 years, the expenditure of the research councils would by 1974/75 have reached a total of about £240 million, which is considerably more than all government departments were spending on civil research (£204 million) in 1964/65. A similar extrapolation of the university figures leads to a total for the universities from the University Grants Committee alone of about £235 million. Thus the combined total for research carried out at universities and by the research councils would be about £475 million in 1974/75—a total which is nearly equal to the estimated combined expenditure on road construction (£192 million) and the whole of the Ministry of Aviation (£299 million) for the year 1965/66.

Table 1. EXPENDITURE BY THE U.K. RESEARCH COUNCILS (£ MILLION)

	1938/9	1947/8	1955/6	1962/3	1964/5
D.S.I.R.	0 89	3 08	6·48	21·87	
A.R.C.	0 32	0·97	4·0	7 71	
M.R.C.	0·22	0·77	2·2	5 86	
N.C.	—	—	0·21	0·66	
	1·43	4·82	12·89	36·10	49·4
Compound annual per cent increase	14 4	13·0	15·8	16·6	

It is conceded by all scientists that the exponential growth of expenditure on science cannot continue indefinitely at a figure (15–20 per cent per annum) which is so out of line with the exponential rate of growth of the G.N.P. of the country as a whole (about 6 per cent per annum at current prices between 1956 and 1965). How can we decide (*a*) when to start cutting back the rate of increase, (*b*) how much and at what rate to cut back, and (*c*) the correct annual rate of increase at which we should finally stabilize?

One obvious line of attack is to examine the figures available for expenditure on all research in various countries and to relate them to the gross national product. For Britain, the relevant figures available are given in Table 3. It will be seen that in 1955/56 the total expenditure by government and industry, private and nationalized, was only 1·64 per cent of the G.N.P. By 1961/62, this had risen to 2·5 per cent, and the best current estimate for 1964/65 leads to much the same figure (2·44 per cent). Over the past three years of this period, total expenditure on research by the four councils and the universities rose from 0·21 per cent of the G.N.P. to 0·28 per cent. Over the same period, expenditure by all industry showed a much smaller rise, that is, from 0·98 per cent of the G.N.P. to 1·04 per cent. Thus the compound annual rate of increase of expenditure by the research councils and the universities (10·1 per cent) was more than five times that of all industry (2·0 per cent) when expressed as a percentage of the G.N.P. Extrapolating these figures, we find that in 1974/75 the research councils and universities would be spending 0·75 per cent of the G.N.P., while the whole of industry would be spending 1·3 per cent. Are such figures reasonable?

We have seen that Britain's total expenditure on research and development seems to have stabilized at around 2·5 per cent of the G.N.P. However, if the rates we have been discussing were maintained, then by 1974/75 all industry together with the research councils and universities would be spending 2·05 per cent of the G.N.P. If we merely maintain all the other expenditure on research as a constant factor of the G.N.P. (1·04 per cent), then the grand total of expenditure on research and development by 1974/75 would be 3·1 per cent of the G.N.P. According to a recent O.E.C.D. investigation, the percentages of the G.N.P. spent on research in 1962 by a number of highly industrialized countries were as follows:

United States	3·1
United Kingdom	2·2
Netherlands	1·8
France	1·5
Germany	1·3
Belgium	1·0

In view of the fact that France and Germany each have achieved an economic situation which is much stronger than the British, it would seem difficult to justify Britain going up to the United States figure of 3 per cent of the G.N.P. in the next ten years, and surely it would be wrong to spend one quarter of that money on basic research. Some decrease in the rate of growth of expenditure by the research councils and the universities on research seems inevitable in the near future.

The techniques used in pure scientific research are becoming more and more expensive as new discoveries in one field become applicable to an entirely different branch of science; for example, nuclear magnetic resonance and the Mössbauer effect, discovered by physicists, are now widely used in chemical research; electron microscopes and computers are gradually being used in nearly every branch of science. This is often referred to nowadays as "the sophistication factor", that is to say, the additional cost required in order to keep a research laboratory up to date technologically.

We might take the figures for a recent three-year period at the National Physical Laboratory to illustrate these trends in salaries and equipment costs. The N.P.L. is sufficiently large and varied to be representative of a cross-section of research laboratories in non-nuclear physics, metallurgy, aerodynamics and ship hydro-

* Preliminary figure.

dynamics, doing a 50/50 mixture of pure and applied research. During the period under review some rather expensive equipment was being acquired (for example, payments for a *KDF* 9 computer of £74,000 were made in 1962/63 and of £148,000 in 1963/64 and the total staff increased from 1,350 to 1,425, nearly 6 per cent in the two years). The cost of new equipment for each scientist went up from £2,670 to £3,350 in two years. In 1956/57, the corresponding figure was less than £1,100. Whereas new equipment formed only 16 per cent of the annual expenditure in 1956/57 that figure had risen to nearly 32 per cent by 1963/64.

The annual increase of 15 per cent in expenditure on basic research by the universities and the research councils must start to drop eventually, but it could be maintained for a few more years if the rate of increase of defence expenditure on research and development were still further diminished. Moreover, for the past four years the expenditure of the Atomic Energy Authority on research and development has been almost constant at about £54 million. If the expenditure is constant (at current prices), this means that the effort is actually being reduced. It could perhaps be further reduced, because several of the tasks for which Harwell and Aldermaston were created have been accomplished.

Table 4. ANALYSIS OF N.P.L. EXPENDITURE (IN £)

	Salaries and wages	Percentage of increase	Equipment	Percentage of increase	Cost of new equipment per scientific officer	Percentage of increase
1961/2	1,378,000		594,000		2,670	
		5		10		25 5
1962/3	1,446,000		651,000			in two
		8·5		22·5		years
1963/4	1,594,000		797,000		3,350	

Undoubtedly the most satisfactory way of producing more money for research and development would be to increase the G.N.P. at a faster rate. The annual growth rate in the G.N.P. of 6 per cent is misleading, because this figure is based on current prices for each year. At constant prices, the real increase in the G.N.P. over the past five years is only about 3·4 per cent per annum. This rate has been surpassed by a considerable factor by countries like Germany, Japan and France, countries which have been devoting a much smaller fraction of their G.N.P. to research and development. Although the United States is the country which devotes the largest fraction of its G.N.P. to research, it must be remembered that this is only so because of a huge programme in space research. If this item is eliminated, then the United States would be spending a slightly smaller fraction of its G.N.P. than Britain. Until about twenty years ago, the United States grossly neglected basic science, yet its applied science and technology were superb and surely played a great part in making its productivity far greater than the British in nearly every manufacturing industry. During the nineteenth century and the early twentieth, Britain was in the forefront technologically as well as scientifically, but we have lost our technological supremacy in many fields, not only to the United States, but to countries like Japan and Sweden. The reasons for this change are many and too complex to be analysed here, but it is generally conceded that we are not getting a sufficiently high fraction of our ablest young men to go into applied science and technology.

Because our battle to reassert ourselves technologically will take some time to win, it is worth considering whether we are making the best use of the government money at present being devoted to civil research, and whether some changes in the distribution of this money might not be made with advantage to our technological and economic future.

* Natural Environment Research Council.
† Social Science Research Council.

An examination of the Civil Estimates for 1966/67 reveals some figures which provide food for a good deal of thought. These are set out in Table 5. It will be seen that expenditure by the Ministry of Aviation on space research is greater than half the total budget of the Ministry of Technology. However, that is not the whole story. Through the Science Research Council an additional £5·5 million is being spent on space research, giving a total of more than £20 million, a sum almost as large as the combined expenditure of the Medical Research Council and the Agricultural Research Council. Is the expenditure of this amount of money justifiable in terms of its returns to Britain scientifically and technologically? It is often argued that "technological fall-out" justifies a large expenditure on space research, and it is certainly a field from which we should not wish to opt out completely and especially because of the potential return in the field of satellite communication. But it is possible to be active in space research with a much smaller expenditure of money.

Nuclear physics is another very expensive field of research. The estimated direct expenditure on nuclear physics by the Science Research Council during 1966/67 amounts to £14·4 million and of this £1·9 million will go as grants to university departments. The total is about 30 per cent more than the total expenditure of the Medical Research Council or the Agricultural Research Council, and more than three times the corresponding sum allocated to chemistry, metallurgy, biology, technology and the rest of physics. Is such an imbalance justifiable? Is it in the best interests of British science and technology? Is it in the best interests of British physics? Would it not be wiser to divert a larger slice of the Science Research Council's cake to solid state physics, to metallurgy, to the environmental sciences, to technology and to chemistry? The technological fall-out from nuclear physics (at least for the next few years) is surely far less than we can anticipate from all these other branches of science on each of which we spend a small fraction of what we spend on nuclear physics.

If therefore we are able to decrease our current expenditure on space research and nuclear physics, it would be quite possible to maintain an annual compound growth rate of 10–15 per cent on university research and the remainder of the research council research work for at least another three years. By this time, the new universities (the creation of which has been partly responsible for the recent steep increase in the bill for university research) might be reasonably well equipped.

BUILDING ON SPRINGS

By R. A. WALLER
W. S. Atkins and Partners, Epsom, Surrey

A CONSTANT source of annoyance that has to be endured by all who live near railways, especially underground railways, is vibration. This is not necessarily so, however, where new lines are being built, or where urban areas are being redeveloped over or alongside railways. Such redevelopment, however, costing each year about £50 million in London alone, represents a considerable problem. Recently in London a building was mounted on springs in order to eliminate vibrations generated by a railway and transmitted to it through the ground (see Fig. 1). The design was to be such as to provide an acceptable level of amenity in what were to be high-quality flats. Similar specifications in further buildings could well require that they also be mounted in this way: a method of establishing whether this is worthwhile has been developed[1].

The problem of mounting a complete building on springs presents the engineer with many interesting and challenging problems. Perhaps the most difficult problems to overcome are the "psychological" ones met in obtaining acceptance for such a scheme. Springs are associated with flexibility and not with the ability to carry load. Now that a precedent has been created it could be that these particular problems will disappear.

When a radical change is made in a well-established form of construction there are likely to be many side effects apart from the obvious problems associated with the design of the springs. The following description will illustrate how many (undoubtedly not all) of these effects and problems were allowed for in the design.

The first step was to define the design requirements, in particular the flexibility required in the springs. This followed from a knowledge of the ambient vibrations in the ground and of the levels of vibration which would be acceptable in the building. The level of vibration in the ground was established by direct measurement using velocity sensitive probes. The ground vibrated predominantly in the frequency band of 20–25 c/s although there were some smaller components at lower frequencies (the overall velocity amplitude was about 0·04 in./sec). These readings were taken while the building that was to be demolished to make way for the new one was still intact. The new building is about the same weight as the old and it was considered that the site conditions would not alter significantly or, alternatively, if there was a change, that the predominant frequencies might be somewhat higher because of the reduction in the mass

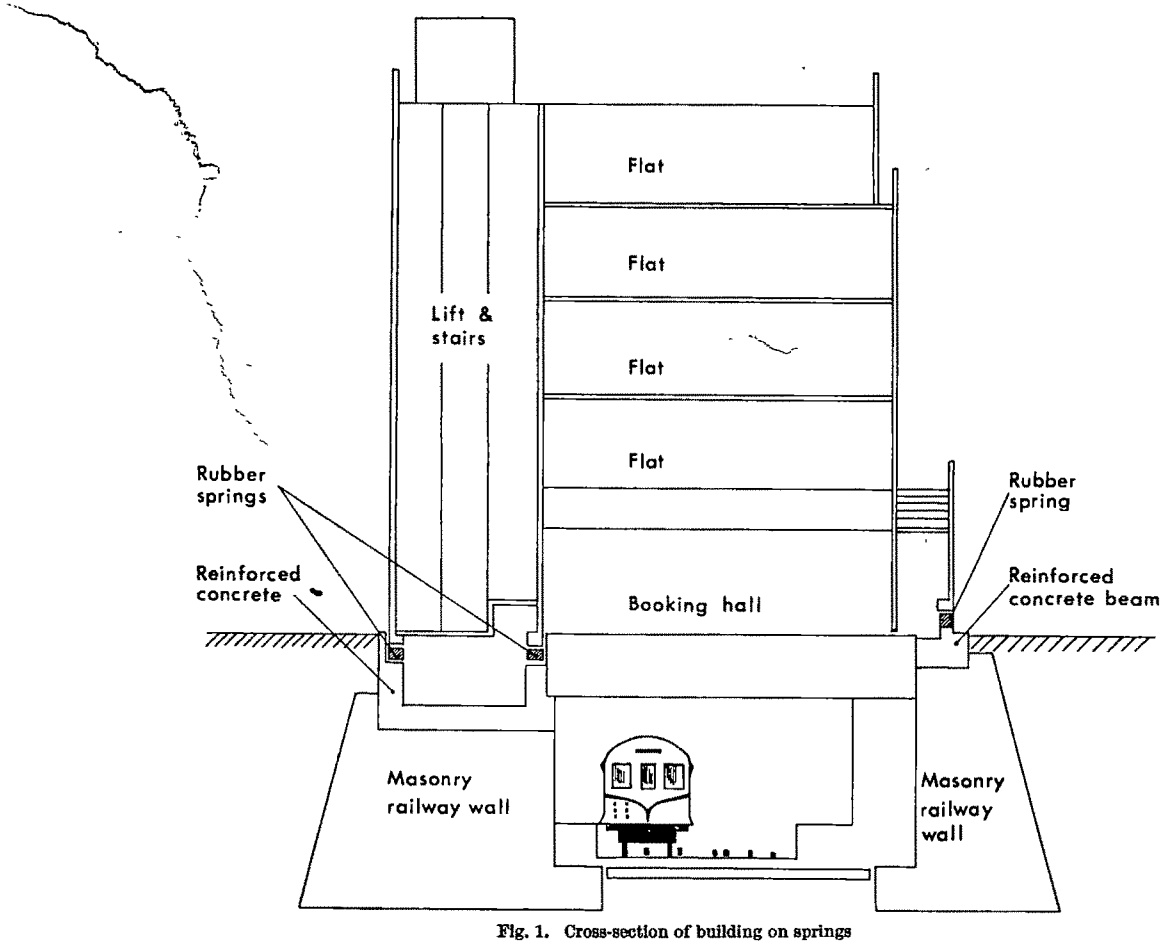

Fig. 1. Cross-section of building on springs

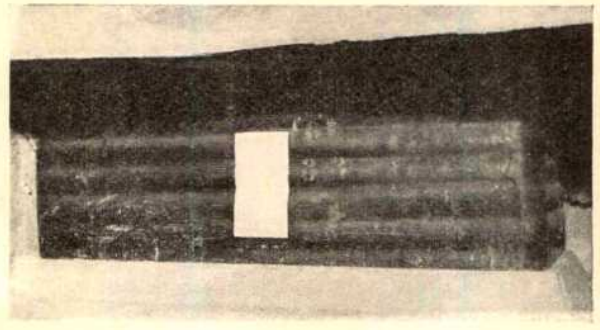

rigidly connected to the ground. (The only change measured on the completion of the new building was that the lower frequency components were slightly more significant.)

The thresholds of perception of vibration have been widely studied[2]. Experiments have been carried out with people standing, sitting and lying down both parallel and perpendicular to the direction of motion. These have almost all been for sinusoidal single frequency vibration which unfortunately in no way represents the pattern of vibrations produced by the trains. At these low frequencies, however, peak velocity seems to be a reasonable measure of sensitivity and this has been used as the criterion. Owing to the considerable variations in sensitivities from person to person it is not possible to fix a level that would be imperceptible to everybody. As with all engineering problems, it was necessary to compromise and the level was fixed (0·01 in./sec) such that only about a sixth of the population could notice the vibrations. The pattern of vibrations generated by the trains consists of a number of peaks superimposed on a background vibration of significantly lower level and the level fixed above was applied to the second highest peak recorded. This was an arbitrary decision made to allow for the transient nature of the vibrations. The difference between the level of the ambient vibration and the level which would be acceptable in the building determined the flexibility required from the springs and the vertical natural frequency of the mounting was fixed at 7 c/s. This allowed for the fact that the low frequency components would be magnified.

Apart from the flexibility the other major requirement for the springs was the ability to carry the load of the building. The flexibility and load carrying capacity determined the type of spring which it would be most economic to use. In this case the appropriate type is a laminated rubber spring with steel reinforcing plates[3]. Rubber is elastic but virtually incompressible—its bulk modulus is much the same as that of water. Between two reinforcing plates the rubber tends to flow outwards restrained only by its shear stiffness (Fig. 2). The shear strain is a maximum at the edge of the plates and limits the load that can be applied and the vertical deflexion. The thinner the rubber layer the more able it is to carry vertical load but the stiffer it becomes. In fact it can be shown* that for given load and stiffness requirements the volume of the springs is approximately constant. This is important because it is the volume which, to a first approximation, determines the cost of an individual spring. The engineer has, therefore, a reasonably free hand to determine the proportions he requires for the springs. At one extreme the rubber layers are very thin and numerous but because of the high load carrying capacity the area of the spring is small; at the other extreme the spring has a large area and consists of one single thick layer of rubber.

Generally it will be found best to equate the compressive stress in the springs to that carried in the [illegible]. This provides continuity of load carrying [illegible] the load does not have to be spread unnecessarily from a column in the building to accommodate a spring. In a reinforced concrete building the compressive stress in the columns will generally be 1,000 lb./in.² and, as in the present building, there is no difficulty in designing the rubber springs to an identical figure. In steel structures the compressive stresses are higher. While some designs of rubber springs have gone up to 2 tons/in.², and while it is theoretically possible to design springs to match the compressive stress carried by steel (10 tons/in.²), it is not at the moment economic to manufacture such springs.

Rubber springs are non-linear their stiffness increases with the speed of loading and their stiffness at small amplitudes is greater than at large amplitudes. Allowance was made for all these factors in the design of the individual springs which entailed a vertical deflexion of 0·4 in. Without these effects an ideal linear spring would have required a deflexion of 0·2 in. Rubber has the advantage, however, of providing damping which is useful in causing a rapid decay in any transient disturbance.

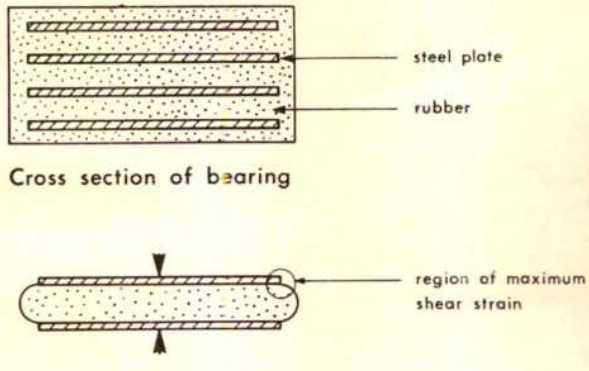

Fig. 2. Rubber spring.

It is worth noting in passing that temperature can have a significant effect on the behaviour of rubber although, in the present instance where natural rubber was used, it was of no significance. The flexibility is affected in two ways. There is an instantaneous increase [illegible]ess as the temperature is lowered; for example, natural rubber doubles its stiffness. Secondly, [illegible] increases gradually with time owing to [illegible]t low temperatures; for example, natural [illegible]rystallize significantly at −20° C. The

* *Note.* Design rules (ref. 4) available for [illegible] expansion movements in bridges gi[illegible] rubber slab:

Ratio dynamic to static stiffness	1·14 (measured)
Ratio stiffness at service amplitudes to stiffness at amplitude used in dynamic test	1·00–1·01 (estimated)
Damping (phase angle)	6° (measured)

Perhaps the paramount problem in designing springs for incorporation in the foundation of a building is the prediction of their useful life. It is quite possible to jack up a building in order to replace the springs, but this is expensive—probably too expensive. There are three major ways in which the life of a laminated rubber spring could be limited and these were tackled in turn as follows:

(1) *Corrosion.* The corrosion of the steel reinforcing plates was prevented by embedding them 0·25 in. into the rubber.

(2) *Atmospheric attack.* Natural rubber is attacked by ultra-violet radiation, oxygen and ozone. Fortunately these are no longer serious problems. The ultra-violet radiation, which might have initiated oxygen attack, is absorbed by the carbon black which is used in the compounding of the rubber. The oxygen attack which results in deterioration of the physical properties of the rubber and the ozone attack which results in the cracking of the rubber where it is strained are both inhibited by the additives used in the manufacture of the rubber. While oxygen and ozone are still, none the less, something of a problem with small sections of rubber (for example, car trims), with the large volumes involved in the springs used here, the main body of rubber is very effectively protected by the outer layers. In particular the critical point at the edge of the bond between the rubber and the steel reinforcing plates is well protected.

(3) *Creep.* It is difficult to estimate the extent to which rubber springs will creep over long periods of the order of 50 years. There are two mechanisms of creep; one results from the oxygen attack which would occur continuously over the years, but in our present springs this can be discounted because of their size. The more important mechanism is due to the effect of loading which produces a creep of approximately 10 per cent of the initial deflexion every decade, that is, every increase in time by a factor of ten. This can be reduced by overloading the springs before putting them into service. In this case with an initial deflexion of 0·4 in. it is estimated that in 50 years the springs might creep a further 0·1 in. from when the building was completed.

It was stated earlier that the introduction of springs into a conventional type of building could have a number of side effects. The effect of rolling a grand piano from one side of the building to the other is fortunately insignificant, but other, perhaps less obvious, effects can cause significant problems. The biggest of these is the effect of wind. Wind loads are not steady and are generated by gusts occurring more or less at random. The problem of wind gusting is one of random vibration and is amenable to some extent to analysis and prediction[5]. Wind gusting can produce significant vibrations in buildings [illegible] it is necessary to examine whether the introduction of flexibility into the foundations might aggravate [illegible] introduce the problem where it might not [illegible] existed.

sary to provide additional lateral springs. While, from the point of view of wind gusting, a higher frequency still would have further reduced the risk of vibrations generated by wind, a higher frequency would have interfered significantly with the isolation of the vibrations borne through the ground in all directions.

Wind can also generate steady vibrations in a building owing to the shedding of a regular pattern of vortices; this generally occurs with fairly rounded shapes or with sections with extreme shapes such as those approaching the flat plate[6]. In this case, with an approximately square shape and with sharp edges, a steady pattern of vortices is unlikely to be set up. The natural frequency chosen to avoid problems from gusting would, as it happens, also prevent trouble on this score because the vortices cannot be generated at a sufficiently high frequency for the amplitude of vibration to build up.

A small margin of safety was allowed in the springs because the vibrations which were borne through the ground occurred at frequencies which correspond with the range of natural frequencies to be found in building components. So far as possible the floors in particular were designed to have natural frequencies away from the frequencies of vibration occurring in the ground. It is virtually impossible to avoid some magnification. However, if severe magnification had occurred, allowance had been made for the construction to be modified and in an extreme case additional damping layers could have been added[7].

Most buildings have to be designed so that in the event of fire they will not collapse before the occupants have had a reasonable chance to get out. It is probable that the rubber springs would burn slowly because of the protection that would be afforded them by a charred outer layer. It is almost certain that they would continue to support a load longer than the structure itself (in any event, stops were provided to limit the settlement of the building to 0·25 in.).

The construction of the building was straightforward; it was built on the springs; the rate of building was kept uniform and materials were stacked where they were to be used in order to ensure that the load was divided between the springs in accordance with the design. Having introduced springs into the foundation it was essential that nothing "bridged" them; all services, for example, sewers and gas, were provided with flexible connexions. In the same way that, for psychological reasons, the major problem in design was obtaining approval for the scheme in principle, during construction, the major problem was ensuring that the gap under the building was not filled with unwanted material. Workmen are accustomed to plugging such gaps and no matter how often they are told they will probably unconsciously continue to fill any gap that can be filled. As much attention needs to be paid to designing unbridgable gaps as to designing cheap and effective springs.

In spite of all these problems the building was completed, [illegible] nobody sensitive enough to feel any vib[illegible] in the building. The economics [illegible] well for a difficult site. The cost [illegible] t 5 per cent (springs alone 2

Interactions of Space Vehicles with an Ionized Atmosphere

Edited by S. F. Singer. (International Series of Monographs in Aeronautics and Astronautics. Division 9: Symposia, Vol. 18.) Pp. viii + 510. (London and New York: Pergamon Press, Ltd., 1965.) 150*s*. net.

THE classical problem of the motion of a particle in a central force field takes on some complications when interactions between more than one such particle have to be considered and when the radial variation of the force is, in consequence, no longer as the inverse square of the distance. This problem has a number of applications—the accretion of electric charge by dust particles in the interstellar gas, the theory of the operation of the Langmuir probe and the development of a satellite wake in the ionosphere. This last example forms the central topic of this book.

The book is based on material originally presented at a symposium of the American Astronomical Society in Washington, D.C., but an attempt has also been made to cover the subject more completely by means of additional papers. In all there are fourteen contributions, divided into two parts. As is often the case with such books, this one presents a difficult problem for the reviewer on account of the varying standard of the contributions, and also of their completeness of coverage, which combine to make it difficult to indicate how thoroughly different portions of the subject have been covered.

Part I deals principally with the interaction with a plasma of a charged body which may be moving. This is discussed in considerable generality in the first contribution by E. J. Opik in a chapter which represents a most valuable contribution to the subject, especially in the discussion of central force fields where the index of the force law is greater than 2. The following chapter, by E. H. Walker, develops the ideas of the first for two applications—the potential distribution about a stationary sphere in a plasma and about a hypersonic moving object. The first of these is the ordinary Langmuir probe; for some reason the greater part of the discussion is for the physically unrealized case in which both ions and electrons are all reflected at the surface of the sphere, though the case which actually occurs is also treated. Results for the moving object—the case of a satellite wake—are also given. It is unfortunate that no comparison with Russian work, that of Al'pert and his collaborators, is attempted as this is in many respects complementary. In fact, it is a noticeable feature of the book generally that the references to other work, particularly that done outside the United States, are often inadequate. This is possibly partly due to its having been a long time in preparation, but it is a weakness.

The next chapter, by R. T. Bettinger, deals with probe methods of measurement in the ionosphere. This is the longest single contribution; from the acknowledgments it appears to have been written as a [illegible] reproduced in its entirety, an im[illegible] review (actually a very p[illegible] any event, it was a cl[illegible]

Soon after the launching of *Sputnik I* a number of different radio-wave propagation effects aroused some interest, such as long-distance reception of the satellite transmitters. Another effect observed by J. D. Kraus at the Ohio State University was thought to be scattering of WWV transmissions from the satellite or its wake, the remarkable feature being the strength of the received signal which corresponded to a scattering cross-section of 10^4–10^6 m^2, several orders of magnitude greater than the geometrical area. To explain this observation provided the original incentive for much of the work on satellite wakes. However, radio signals are also reflected from ionized meteor trails, and the association of some signals with satellites has always been controversial. Part II is devoted to this topic, and the first three contributions (by J. D. Kraus, by T. G. Hame and W. D. Stuart, and by T. A. Croft and O. G. Villard) describe different experimental investigations of this correlation. In the work by Kraus, an effort is made to correlate specific strong bursts with satellites; it is concluded that positive results are obtained. In the next two papers a more statistical approach is used but negative conclusions are reached—neither investigation yielded effects which could be ascribed with certainty to a satellite. The general impression left on the reader is that this conclusion is more likely to be correct. The next three papers (by E. H. Walker, by L. Peters and W. G. Swarner, and by K. M. Chen) discuss the calculation of the scattering of electromagnetic waves by a satellite wake. Rather oddly, in view of the above conclusion, it is found that because of the rod-like form of the trail sufficient energy might be focused in an approximately normal direction to give effects comparable with those observed.

The uneven quality of its subject-matter makes it difficult to recommend this book without reservations, though, at best, as in the chapter by Opik, it is very good. The subject-matter for the most part covers a rather narrow field and will, therefore, interest specialists. On the other hand, three contributions have some general application in astronomy and plasma physics and will attract a wider audience. The index is comprehensive and, for the most part, well selected. A. P. WILLMORE

QUANTUM APPROXIMATIONS

JWKB Approximation

Contributions to the Theory. By Nanny Froman and Per Olof Froman. Pp. viii + 138. (Amsterdam: North-Holland Publishing Company, 1965.) 32*s*.

THE subject of this book is the mathematical approximation method, which to most authors in theoretical physics is known as the Wenzel–Kramers–Brillouin (WKB) method. Apart from an orthodox derivation of the WKB formulae in Chapter 2, the book is based entirely on the original work of the authors.

Their aim has been to provide a mathematical apparatus [illegible]gorous treatment and systematic applica[illegible]. In this, they have added considerably [illegible] of the method. The important [illegible]imits of error in applications [illegible]d is clearly discussed in

The general solution of this system of equations is obtained in the form of four convergent series expansions. For the derivation of the exact solution and subsequent discussion of its properties (Chapters 4–7) a particularly elegant matrix notation is introduced which greatly condenses and simplifies the presentation.

In the final three chapters (9–11) the important points emerging from the general theory are illustrated by detailed applications to some well-known physical problems; these are barrier transmission problems, the bound states of a particle in a potential well, and the radial wave equation for a spherically symmetric potential.

The material in this book, which is clearly presented and well illustrated with contour diagrams, should be of interest to many theoretical physicists. D. W. Wood

HYDROGENATION

Catalytic Hydrogenation

Techniques and Applications in Organic Synthesis. By Robert L. Augustine. Pp. xii+188. (London: Edward Arnold (Publishers), Ltd.; New York: Marcel Dekker, Inc., 1965.) 72*s*. 6*d*. net.

For more than half a century the techniques and mystiques of catalytic hydrogenation have been fruitfully used in synthetic organic chemistry, and a great deal of information of what catalyses which reaction and under what conditions lies scattered throughout the chemical literature. Dr. Augustine has performed a useful function in summarizing what is known in this field and presenting it in a form which will be readily assimilated by experimental organic chemists.

After a brief introduction, Chapter 2 treats apparatus and techniques with quite detailed descriptions of equipment used both at atmospheric pressure and at elevated pressure, with proper emphasis in the latter case on safety precautions. Chapter 3 deals with catalysts and conditions; the preparation, properties and catalytic usefulness of hydrogenation catalysts in common use (Raney nickel, copper chromite, Adams platinum oxide, palladium on charcoal, etc.) are described. The reader could, however, be pardoned for forming the erroneous impression that there is only one manufacturer of supported noble metal catalysts.

It is in the second part of this chapter that Augustine's presentation is weakest. The proper choice of reaction conditions is of paramount importance in determining the yields of products, but the effect of agitation is dismissed in one sentence without mentioning diffusion or transport control, and although efficient use of the catalyst is clearly not a prime consideration in preparative organic chemistry, it is well established that agitation conditions can effect selectivity in multi-stage reactions. The effect of temperature is likewise dismissed somewhat lightly. There is no mention of the fact that the increase in vapour pressure of the solvent with temperature serves to reduce the partial pressure of hydrogen and that this can under certain circumstances give an apparently negative activation energy. The effect of quantity of catalyst is also discussed without reference to diffusion limitation in a monumentally cumbersome sentence. The author's style in this section is often obtuse, and sometimes ambiguous. The sentence (page 46): "All hydrogenations, except that of nitro groups, in which a nickel catalyst is used, increase in rate with the addition of base", besides being ungrammatical, is capable of two distinct interpretations: such is the power of the mighty comma!

There follow two chapters on the hydrogenation of functional groups in which the author considers in turn the various reducible groups encountered in organic chemistry: he starts each section by stating a general recipe for the hydrogenation, and subsequently enlarges and qualifies this by means of illustrative examples. Perhaps wisely, the author eschews any mechanistic discussion, although some further attempt at rationalization of the observations would not have come amiss. It is, however, these two sections, and the following chapter on hydrogenolysis, which will be most widely appreciated and used.

It is commonplace, to-day, to complain of the price of scientific books: many, I fear, will wonder whether 72*s*. 6*d*. is not too high a price to pay for less than 200 pages, whatever their value. G. C. Bond

LIVING STRESS

The Physiology of Human Survival

Edited by O. G. Edholm and A. L. Bacharach. Pp. xxii+581. (London Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1965.) 140*s*.

In their introductory remarks the editors state that this book arose from discussions between themselves about the factors affecting the survival of the individual and his ability to adapt to changing conditions. They have gathered together articles by sixteen writers, physiologists and psychologists, relating primarily to the responses of human beings to a wide variety of external and internal stresses ranging from those of extremes of temperature and pressure on the one hand to sleep deprivation and pregnancy on the other. The editors aimed at bringing together all the important information at present available on the effects of environmental stress on man including, where it is necessary for a more complete understanding, accounts of the effects on other mammals. It is relatively easy to pick out areas which have not been dealt with in this book, but the editors point out that they did not intend it to be all-embracing and in certain respects it may be regarded as being complementary to the volume in the Handbook of Physiology series published by the American Physiological Society on *Adaptation to the Environment* which dealt with the whole animal kingdom. The contributors were asked not to produce a complete review of their subject but rather to concentrate on their own fields of research within the subject allocated to them. This request has been met by a variety of responses so that the scope of the articles ranges from a comprehensive review of the effects on man of deficiencies and excesses of water and salt intake by W. S. S. Ladell to a relatively detailed account by J. D. Hatcher of his own work on the humoral mechanisms responsible for the increase of cardiac output induced by acute anoxic anoxia.

The first six chapters of the book deal with the responses of man to stresses associated with changes in his physical environment. The first two chapters, one on the effects of cold by L. D. Carlson and A. C. L. Hsieh, and the other by R. H. Fox on the effects of heat, reflect the different interests of these authors. Thus, while the chapter on cold is based on a mathematical treatment of heat exchange, Fox deals at length with the problems of finding a reliable index of heat stress and the techniques for studying and determining the physiological changes responsible for heat acclimatization. Hatcher's account of the cardiovascular and respiratory responses to acute anoxia is followed by a comprehensive description by L. G. C. E. Pugh of the adaptive responses to hypoxia which occur on prolonged exposure to high altitudes. A brief review of the physiological effects of exposure to high pressures by H. J. Taylor shows the many phenomena in this field which invite further study. Progress in one particular field is illustrated by P. B. Bennett's article on the narcotic action of inert gases. An authoritative account by P. Howard of the effects of high and low gravitational forces brings out the contrast between extensive present-day knowledge of the mechanisms which underlie man's reactions to the stress of increased gravitational field and the paucity of

information concerning the physiological effects of the weightless state.

The second section of the book consists of articles which deal with nutritional stress and exercise. In a discursive review of nutritional changes, R. A. McCance and E. M. Widdowson point out that man has himself created the nutritional stress of a surfeit of calories. There follows W. S. S. Ladell's extensive account of the effects of the disturbance of water and salt balance. J. V. G. A. Durnin presents in a provocative chapter an objective evaluation of the value of exercise, and emphasizes the need for adequate physical exercise in modern society. A chapter by F. E. Hytten and A. M. Thomson on the stress of pregnancy presents a summary of the physiological changes which occur in this condition, and discusses in detail the associated changes of food stores and energy requirements.

In the next section of the book, Mary C. Lobban calls on the wealth of experimental data which she has collected in her studies at Spitsbergen to present some of the challenging problems associated with the 'biological clocks' of the human organism. R. T. Wilkinson describes the difficulties which have been encountered in attempts to demonstrate physiological and biochemical changes as a result of deprivation of sleep. Indeed, he points out that it has only recently been possible to demonstrate objectively the decrement of performance of which one is aware after a sleepless night.

In a stimulating article A. T. Welford describes the present state of knowledge with respect to the psychological and physiological mechanisms involved in fatigue. This chapter, taken in conjunction with the succeeding one by S. M. Hilton, in which he describes his studies on the neurophysiological mechanisms underlying emotional expression, demonstrates how the artificial barriers which have for so long separated psychology and physiology are being broken down.

The final chapter of the book by R. W. Brauer, which is entitled "Irreversible Changes", emphasizes the areas in which further experimental work is required in order that the physiological processes which underlie human reactions to stress may be better understood.

I enjoyed reading this book and it will no doubt be of value to those concerned with human biology. The specialist working in one of the more applied fields of human physiology will find much of interest, particularly in regions other than that with which he is directly concerned. The editors are to be congratulated on the result of their efforts to obtain uniformity of expression between the sixteen contributors to this book. J. ERNSTING

BREATH OF LIFE

Oxygen

(Proceedings of a Symposium sponsored by the New York Heart Association.) Pp. 283. (London: J. and A. Churchill, Ltd., 1965.) 42*s*. 6*d*.

FEW substances are as familiar as oxygen. With these words the chairman of the symposium committee begins his general introduction to the proceedings of a symposium sponsored by the New York Heart Association. Let us hope the spate of books on the biological importance of oxygen does not make us contemptuous. However, this volume makes a valuable contribution to a most important field, despite its appearance so soon after the larger work, *Oxygen in the Animal Organism*, published in the International Union of Biochemistry Symposium Series.

The work is divided into four parts, each introduced by an eminent authority and followed by a discussion.

In the first part, introduced by D. Rittenberg, M. Dole describes the "natural history" of oxygen, beginning with its cosmic generation and going on to the formation of molecular oxygen in the Earth's atmosphere. The main part of the first paper is concerned with an attempt to quantitate the mechanisms for the production of molecular oxygen. The first of these before the appearance of life on Earth is the photolysis of water vapour and the second photosynthesis. The production of oxygen permitted the appearance of other living systems for two reasons: it provided an energy-producing mechanism, the reduction of molecular oxygen, and in addition the appearance of oxygen, at about 1 per cent of the present level, was followed by the formation of ozone, which acted as a barrier to ultra-violet light. This event occurred in the Cambrian era and was followed by an "evolutionary explosion".

The second paper, by H. Taube, is concerned with mechanisms of oxidation with oxygen. It begins with a discussion of the relevant aspects of the electronic structure of oxygen and goes on to consider oxidation mechanisms generally as biological models.

The second part, on oxygen-transporting pigments, is introduced by R. Forster. Only two pigments are considered: haemoglobin and myoglobin. They illustrate two different types of transport mechanism. Haemoglobin transports oxygen in the blood from the lungs to the tissues by increasing the capacity of blood for oxygen, whereas myoglobin in the tissue facilitates the transport of oxygen by a rather different mechanism. That myoglobin may facilitate the diffusion of oxygen in tissue is a recent hypothesis, and J. Wittenberg considers some of the possible mechanisms. In the second paper in this section, P. Urnes discusses the important question as to how far the magnificent work on the structure of crystalline myoglobin is relevant to the structure of the molecule in solution. From observation of the ultraviolet optical rotatory dispersion of the solution, he concludes that no appreciable change in conformation occurs on solution. F. J. R. Roughton's masterly account of recent work on haemoglobin closes this section. His main theme is the possible role of aggregation of the haemoglobin molecule on oxygenation. There seems to be a range, from the lamprey, in which aggregation is of fundamental importance to the reaction, to the sheep, whose haemoglobin shows minimal change of aggregation on oxygenation.

V. Dole introduces the third section, on oxygen consumption in the cell. In the first paper, entitled "Oxidation and Peroxidation", P. Nicols considers the reaction of the haem enzymes with molecular oxygen and discusses a different kind of theory of the mechanism. R. Butow and E. Racker, in their paper on the mechanism of respiratory control, discuss the properties of their new model in which the "loosely coupled' sub-mitochondrial respiratory particle is made "tightly coupled" by the addition of *o*-phenanthroline.

The section is closed by B. Chance, who considers the way in which the oxygen and control reactions described in the previous two papers could co-operate to establish a purposeful metabolic control *in vivo*.

The final section, introduced by S. Granick, is entitled "Non-Haemoproteins and Oxygen". In the first paper, Q. Gibson describes the mechanisms of reaction of some flavoprotein enzymes with oxygen. These differ from the haem enzymes in that oxidation and reduction involve two equivalents and the evidence for the existence of intermediately oxidized forms is considered. In the second paper, E. Frieden, S. Osagi and H. Kobayashi survey the interaction of the copper proteins and oxygen and consider the correlation between structure and function. Finally, H. Goldfine in his paper "The Evolution of Oxygen as a Biosynthetic Agent" presents a completely different aspect of the biological role of oxygen. All the other papers were essentially concerned with the role of oxygen in bioenergetics, but this final paper considers it as a synthetic agent, as an integral part of cell constituents.

Each of the four sections is followed by a general discussion, which has clearly been carefully edited but without losing the spontaneity of some of the comments. The book is well printed and reasonably well bound; the index, however, contains some errors but it is of a higher standard than is sometimes found in published proceedings. I. S. LONGMUIR

STAFF OF RUSSIAN LIFE

Biochemistry of Grain and Breadmaking

Edited by V. L. Kretovich. Translated from the Russian by N. Kaner. Edited by E. Seijffers. Pp. xi+259. (Jerusalem: Israel Program for Scientific Translations; London: Oldbourne Press, 1965.) 81*s*.

FOOD technologists, plant breeders and cereal chemists in particular will read this book with interest and profit. It is a collection of thirty papers read at the All Union Conference on Biochemistry and Breadmaking in Moscow in 1960. The Conference was held by a decision of the twenty-first Congress of the Communist Party of the Soviet Union as part of the National Seven Year Plan. Twenty-six of the papers are concerned with wheat and the remaining four with maize, rice, barley and sorghum. The Conference was held in 1960 and it is easy to say that the papers are now dated. This would be most misleading. Some of the problems may have lost a little of their novelty, but they still remain, and this book brings them together, defines them very clearly and, wherever possible, relates them.

The Conference was opened by N. M. Sisakyan, biological secretary of the Academy of Sciences, who stated that the Soviet Union is "a grain producing world power with unlimited possibilities", and in which "the crop yields and grain quality should be the highest in the world". He read out two resolutions approved by the Academy of Sciences, one of which is certainly worth pondering over: "The importance of a more concentrated effort in tackling the major research problems must be impressed on scientists and scientific organizations. They must be encouraged to display the maximum possible initiative and creative ability, and must keep informed on the progress of science and participate in the discussions taken on the scientific research policy".

A masterly paper by Prof. Kretovich opened the Conference and outlined the scope of the field of research involved in the decision of the twenty-first Congress. Here and there he highlighted certain aspects with important practical applications, such as the possibilities of breeding maize and wheat with a high lysine content, the protein complex of flour and the changes it undergoes during breadmaking, and the proper drying of damp grain. He also emphasized the part that electronics can play in the development of automatic analytical methods for use in the handling of cereals and in the operations of milling and baking.

It is invidious to single out individual papers, but I read with particular interest that on the effects of irradiation on the baking properties of wheat by Sosedov and Vakar, on the biochemical effects of wheat conditioning by Zotova and Kretovich, on the structure of cereal proteins by Reznichenko, and on the action of oxidizing and reducing agents on gluten by Shklovskii. Another paper, by Auerman *et al.*, in making a strong case for the widespread use of ascorbic acid as a bread improver, is of particular interest in Britain in the light of recent developments in rapid breadmaking in which ascorbic acid is an essential ingredient.

My most striking impression is perhaps the close similarity both of the problems and of the manner in which they are being tackled in the U.S.S.R. and in Britain. This perhaps is not surprising, yet apart from some references to the work of Chibnall and Sanger on the chemistry of proteins, there are practically no references to papers published outside the Soviet Union. But then how many references to Russian work would be found even in a review paper on any aspect of cereal chemistry published in Britain? The book certainly suggests that an International Scientific Conference focused on the staff of life would present no difficulties over a programme, would be well worth while, and any recommendations regarding future research would be unanimous. As Academician Sisakyan pointed out, the biochemistry of grain and that of breadmaking are of the utmost scientific and practical importance and play a major part in his country's economy. In this respect the U.S.S.R. is not unique. T. MORAN

Weak Interaction of Elementary Particles

By L. B. Okun'. Translated from the Russian by S. and M. Nikolić. Translation edited by J. Bernstein. (International Series of Monographs in Natural Philosophy, Vol. 5.) Pp. x+292. (London and New York: Pergamon Press, Ltd., 1965.) 60*s*. net.

THIS book by Prof. L. B. Okun' of the Institute of Theoretical and Experimental Physics, Moscow, is intended for graduate students who are specializing in high energy physics. It really starts from the beginnings of the subject, so that it can be put into the hands of a research student as soon as he starts work, provided only that he has had a reasonable general grounding in quantum mechanics.

In just under three hundred pages it goes systematically through the subject of weak interactions. It starts with a general discussion of the fundamental interactions and defines the operations of space, time, and particle (charge) reversal. Then follows a series of chapters on pure leptonic, semi-leptonic and non-leptonic decays. Calculations are presented in considerable detail, and there is no resort to "it can be shown" or "it is easy to see".

The book is based on lectures originally given in 1960 and still carries the flavour of that period with its major emphasis on parity non-conservation. Some revision has been made during the translation in 1964, which consists mainly of a long additional chapter on unitary symmetry. There is, of course, no mention of the recent discovery that charge-parity is also not universally conserved. This matters less than it might, because it has not yet been incorporated in any satisfactory way into the general theory, but remains for the moment an isolated freak effect of the neutral K-complex.

Okun' is one of the best-known high-energy theoretical physicists of the U.S.S.R. with a world-wide reputation for his clear thinking and incisive critical approach. The translation has been edited by J. Bernstein, also a high-energy physicist of international repute, who has contributed to the *New Yorker*, and takes a pride in finding the felicitous phrase. The result is something rare—particularly when the transition is from Russian into English—a first-rate translation of an excellent book.

P. T. MATTHEWS

Selected Problems in Quantum Mechanics

Collected and edited by D. ter Haar. Revised and augmented second edition of Gol'dman, Krivchenkov, Kogan and Galitskii, "Problems in Quantum Mechanics". Pp. vii+402. (London: Infosearch, Ltd., 1964. Distributed outside the U.S.A. by Macmillan and Co., Ltd., London.) 50*s*.

THE second edition of this excellent collection of problems is certainly to be welcomed. The problems, with detailed solutions, cover most aspects of non-relativistic quantum mechanics, with a range of difficulties covering the whole spectrum of undergraduate and postgraduate teaching. The changes from the first edition are an increase in the number of problems from 333 to 404 and a greatly improved typography.

A collection of problems such as this is usually consulted both to test one's knowledge and to further it. In many ways these are separate functions, and perhaps the only real criticism of the book is that the two functions are not separated well enough. Undergraduate students in particular would often want to use the book as a practice for examinations, and it is a pity that the simpler problems are not differentiated from the others in some way: often the only way for such a student to discover that an apparently simple problem requires mathematical techniques beyond his ability, apart from wasting hours of effort, is to look firstly at the solution in the back of the book! On the other hand, more senior students who are using the book as advanced reading might well prefer the difficult problems to be clearly grouped together in each chapter.

This is a small point, however, which should not prevent this second edition being as widely read as the first, as it well deserves. F. H. READ

Ultrasonic Engineering

By Julian R. Frederick. Pp. xii+379. (New York and London: John Wiley and Sons, Inc., 1965.) 113*s*.

THE author of this book is an associate professor of mechanical engineering in the University of Michigan and as therefore might be expected he deals very competently with the engineering aspects of ultrasonics. He has also had the earlier benefit of being associated with Firestone when the latter was developing his ultrasonic flaw detection systems, and so Chapter 7 dealing with this subject is a very authoritative contribution to the literature. Inevitably, through compression into a single chapter, the basic theory has suffered somewhat in places through inadequacy of explanation, but these are small blemishes in a book which is written in a lucid style and where the text is supported by excellent line diagrams. It contains a wealth of practical and theoretical information which is by no means restricted to American sources. There is an excellent set of references and a most useful guide to ultrasonic literature which the growing field of users of ultrasonics will find invaluable.

R. W. B. STEPHENS

Parliament and the Executive

An Analysis with Readings. By H. V. Wiseman. Pp. xvi+271. (London: Routledge and Kegan Paul, Ltd., 1966.) 18*s*.

APART from an introduction, largely historical, of 46 pages, this book consists of 120 short extracts from writings about the relations between Parliament and the executive. They range from standard authorities such as Dicey and Bentham, Bagehot and Mill to the current writings of Sir Ivor Jennings, D. N. Chester, K. C. Wheare and Lord Campion, and are classified in eleven sections dealing with such subjects as collective and individual ministerial responsibility, the power of the Cabinet, the role of the House of Commons, questions and the use of committees. Scientific aspects of the formation of policy are not specifically discussed in these extracts, although the introduction shows some awareness of these aspects in explaining the choice and arrangement of the extracts. There is in fact little of direct interest to the scientist in this book and, while the variety of the extracts indicates the extent of the field to be considered, the work is unlikely to prove more satisfactory for the general reader. The extracts generally are too short and the introduction fails to gain the coherence which a well-chosen anthology should possess. To those embarking on a first study of British history or politics it may well provide a useful introduction to the literature, but Prof. Wiseman contributes disappointingly by way of criticism himself, though his selection of extracts is representative and well designed to assist the formation of a sound opinion on the role of Parliament in relation to the increased power of the executive. R. BRIGHTMAN

MEETINGS

DRUGS FROM ANIMALS

THE first international symposium on "Drugs of Animal Origin" was held at the Istituto di Ricerche Farmacologiche Mario Negri in Milan, during May 12–13, organized by Prof. Garattini (chairman) and Prof. Leonardi (secretary). As expected from the all-embracing nature of the title, the topics discussed varied enormously. They ranged from recent developments in the chemistry and pharmacology of hormones in well-established endocrine fields, to the introduction of new concepts about the part played by the body as its own pharmacologist and dispensing chemist.

The prostaglandins provided the largest single topic, and Prof. Bergstrom (Karolinska Institutet, Stockholm) opened the discussion with an excellent review of the present knowledge of their structure, biosynthesis, and metabolism. With this knowledge available, Dr. Vogt (Max Planck Institut, Germany) extended the scope to the release of prostaglandins from guinea-pig lung by cobra venom and by such milder stimuli as hypertonic saline. It would appear that prostaglandins provide a normal constituent of the slow-reacting substance released in this manner. The wider distribution of prostaglandins outside the site from which they take their name (the prostate) was clearly shown both by Prof. Horton (St. Bartholomew's Hospital Medical School, London) and by Dr. Paoletti (University of Milan). Prof. Horton's work demonstrated the presence of various prostaglandins in the central nervous system of the cat and the fowl, and showed the unusual pharmacological responses which injection of these drugs can induce. Dr. Paoletti's work was concerned with the systemic pharmacological and biochemical actions (for example, on blood pressure, heart rate, mobilization of glucose).

Another subject dealt with by a number of authors was the control of blood calcium levels. Until quite recently it was believed that the level of blood calcium was essentially under the control of parathormone—the hormone of the parathyroid gland. Dr. Aurbach (National Institutes of Health, Bethesda) presented a summary of the chemical, biological and immunological properties of parathormone, and suggested a probable structure. However, another hormone, thyrocalcitonin, has recently been isolated from the thyroid gland, and has been shown to possess an important plasma calcium-lowering property. This topic was briefly mentioned by Dr. Andreoli (Istituto di Patologia Medica, Rome) when considering the broader aspects of synthesis, metabolism and actions of thyroid hormones. A more detailed study was given by Dr. MacIntyre (Postgraduate Medical School, London), who described classical endocrine experiments in which perfusion of the vascularly inseparable parathyroid/thyroid gland of the dog was performed. Perfusion with blood containing high and low calcium levels resulted in low and high systemic blood levels respectively. Use of the goat (in which the thyroid and parathyroid glands are anatomically separate) strongly suggested that the hormone is secreted by the thyroid. The hormone was shown to act independently of the parathyroid hormone, and to produce its effect by increasing bone uptake of calcium, an effect probably arising from a reduction in the breakdown of bone. The possible clinical applications of thyrocalcitonin in hypercalcaemia and other diseases in which calcium metabolism is upset were discussed, both by Dr. MacIntyre and by Dr. Milhaud (Institut Pasteur, Paris), but so far only limited clinical results are available.

Other subjects discussed show the varied nature of the meeting. Dr. Schofield (Royal Veterinary College,

London) presented evidence obtained from experiments in guinea-pigs and sheep which demonstrated the action of the placenta on the myometrium, and indicated its possible function in labour. Dr. Jung (Universität Frauenklinik, Germany) demonstrated a substance of myometrial origin which activated the rat uterus, while inhibiting the human uterus.

Prof. Robson and Dr. Robinson (Guy's Hospital Medical School, London) presented evidence for the presence of an anti-inflammatory substance at sites of inflammation, with some preliminary data on its possible chemical nature. Dr. Masek (Institute of Pharmacology, Prague) described the pharmacological effects of palmitoyl ethanolamide, a compound which occurs naturally in some mammalian tissues, and which has been shown to possess anti-inflammatory, anti-anaphylactic, and analgesic actions.

Several papers dealt with various aspects of assay techniques used to estimate trophic factors associated with central control of endocrine function. Dr. De Wied (University of Utrecht, The Netherlands) reviewed the *in vivo* and *in vitro* methods available for the assay of corticotrophin releasing factor. Prof. Martini (University of Milan, Italy) then discussed a new technique known as the "pituitary depletion method", which has recently been developed in his department. This enables simultaneous evaluation of the activity of hypothalamic extracts on all pituitary hormones, and has facilitated investigation of the physiological significance of the hypothalamic control factors. Finally, in this sphere, advances in the techniques of extraction, separation and purification of human follicle stimulating hormone were reviewed by Dr. Reichert (Emory University, U.S.A.), who then went on to discuss the value of available biological assay methods. The preparation of purer samples of follicle stimulating hormone has, over recent years, made possible much greater accuracy in therapeutic dosage in cases of amenorrhoea, thus reducing the risk of multiple ovulation.

B. V. ROBINSON
J. M. ROBSON

NON-LINEAR ACOUSTICS

SIXTY-TWO people attended the one-day symposium on non-linear underwater acoustics, sponsored by the newly formed British Acoustical Society and organized on its behalf by Professor D. G. Tucker, which was held in the Department of Electronic and Electrical Engineering at the University of Birmingham on July 19. Professor Tucker took the chair for the morning session and Dr. R. W. B. Stephens (Imperial College of Science and Technology) in the afternoon.

Three of the five papers presented discussed the sound field arising from the interaction of two coincident acoustic waves. Professor S. Tjøtta (University of Bergen) presented a rigorous mathematical analysis based on the hydrodynamical equations while Dr. H. O. Berktay and Mr. B. V. Smith (University of Birmingham) gave alternative (and simplified) engineering approaches to the same problem. These papers showed that, as a result of the non-linear relationships of acoustic pressure with density on one hand and compressibility on the other, two coincident plane (or spherical) primary waves of differing frequencies produce virtual sources in the water at the harmonic and intermodulation frequencies. These virtual sources form a virtual acoustic array in the medium itself, and Dr. Berktay discussed in detail some possible transmitting applications of the virtual array formed at the difference frequency and illustrated these by experiments. He showed that a number of desirable results could be obtained economically, including high directivity at low frequencies with small transducers and a substantially constant beamwidth over a wide range of transmitted frequencies. These possibilities could completely revolutionize the design of echo-sounders, wide band sonars and transmit-beam scanning sonars. A small scale model of a non-linear sonar system was also demonstrated; a narrow beam of acoustic waves at a frequency of 100 Kc/s was formed from two primary waves in the region of 3 Mc/s. Professor Tjøtta made the further point that if one of the primary waves was used as a "pump" and the other consisted of an echo-signal from a distant target, parametric amplification of the weaker signal could be effected. During the discussion, the similarity between the parametric amplification of acoustic and electronic travelling waves was noted, particularly in regard to the need to suppress the sum frequency wave.

Mr. R. T. Smith (Imperial College of Science and Technology) showed that an initially sinusoidal wave of high amplitude becomes progressively more triangular owing to changes in the velocity of propagation of various parts of the wave. He also discussed the formation of shock waves in liquids and related this to the physical properties of the medium.

In the final paper Dr. V. G. Welsby and Mr. M. H. Safar of the University of Birmingham described investigations of the generation of harmonic and subharmonic frequencies when the amplitude of a single primary wave is increased to the region of the cavitation threshold of the medium. As the acoustic pressure is increased, the subharmonic level increases; but sometimes on approaching the cavitation threshold the subharmonic decreases slightly and then, after cavitation, rapidly increases. (On other occasions the dip near cavitation is less pronounced or even entirely absent; the factors governing its appearance have not yet been fully investigated.) On the basis of their experiments the authors posed a number of questions about the physical mechanisms involved, and discussion made it clear that there is considerable uncertainty on this topic.

The British Acoustical Society seems to have got off to a good start with a successful first meeting.

B. K. GAZEY

OBITUARIES

S E. Hollingworth

THE sudden death in London on June 23, 1966, of Professor Sydney Ewart Hollingworth, on the eve of retirement after 20 years in the Yates-Goldsmid chair of Geology at University College, London, was a shock to his many friends. He was the twelfth well-known British geologist to die since March 1965. Before becoming professor he had served 25 years with the Geological Survey of Great Britain where he had established a high reputation as a field geologist with an independent and critical outlook.

He was born on November 7, 1899, and educated at Northampton School. After a short period of Army service, he went to Clare College, Cambridge, in 1918, where he graduated with first-class honours in both Part I and Part II of the Natural Sciences Tripos, and in 1921 he was awarded the Harkness Scholarship. In the same year he took the external B.Sc. honours degree of the University of London and joined the Geological Survey. In his first winter he revised some of the geological boundaries for publication of the Shaftesbury one-inch map. Hollingworth then took his place in the Survey's Cumberland unit first under B. Smith and later T. Eastwood to become part-author of the Carlisle, Brampton, Whitehaven, Gosforth and Cockermouth maps. Besides studying the Ordovician, Carboniferous and other bedded rocks, he showed that the Ennerdale Granophyre was a

stock and not, as previously supposed, a laccolith. He identified the components of the Carrock Fell igneous complex and inferred that they were intruded as steeply inclined sheets or elongated lenses after the main Caledonian folding and during a trough-like subsidence of the region. He also threw light on the glacial retreat phenomena of western Edenside and the Solway Basin, drainage problems of the River Eden and solifluxion phenomena. Inspired by data from Cumberland he made a statistical analysis of high-level erosion surfaces in Britain.

After two years spent mapping in the Droitwich neighbourhood he was transferred to work on the one-inch maps of the Huntingdon and Cambridge areas. In the war years he worked mainly on the structure, stratigraphy and reserves of the sedimentary iron ore field developed in the Northampton, Wellingborough and Kettering areas. As a substantial legacy to geology he contributed a demonstration, with other colleagues, that some structures revealed in the Jurassic rocks in the ironstone field were superficial Pleistocene features caused by adjustment forces producing valley bulging and valley side cambering. In all, Hollingworth was part author of twelve of the Geological Survey's one-inch maps as well as a memoir on gypsum and anhydrite. The latter subject he amplified later when dealing with facies problems in the Permo-Triassic related to evaporite deposition and stratal correlation.

Hollingworth was selected for the Geology Chair at University College, London, in 1946, in succession to W. B. R. King, who moved to Cambridge. He proved to be an invigorating teacher. His special attributes were to develop competence in field geology and an appreciation of the industrial applications of the subject. He initiated research by his students in south-west Ireland and, subsequently, he established research groups in the Caledonian orogenic belt of northern Norway and later in Chile.

Hollingworth had exceptional gifts in debating the results of almost any geological research and thus was a stimulating but always friendly critic. These gifts were canalized into the affairs of the Geological Society of London, which he served as Secretary from 1949 to 1956 and as Vice-President (1956–58 and 1962–64). He was President from 1960 to 1962 and received the Society's Murchison Medal in 1959. He leaves a widow and two sons.

C. J. STUBBLEFIELD

Prof. P. Maheshwari

THE sudden and untimely death of Professor Panchanan Maheshwari on May 18, 1966, at Delhi, where he was head of the Department of Botany at the University, is a sad loss to botany not only in India but throughout the world. His was a dynamic and stimulating personality and nobody who met him could fail to be impressed by his energy, sincerity and simplicity, even if these good qualities were occasionally masked by an arrogance that could be misunderstood by those who failed to see beneath it. Maheshwari was a man of boundless energy and high ideals who set himself and his colleagues a very high standard in all the scientific work which they undertook. He could tolerate nothing that was second rate and he did not mince his words when he encountered inefficiency or obstruction in any shape or form. He was a good teacher with a broad outlook who not only inspired but also really cared for his students, who held him in high regard. And yet this broadness of vision was accompanied by ability to conduct research of a very high order in a specialized field, and his life's work on the embryology of plants is known throughout the botanical world.

Maheshwari was born at Jaipur on November 9, 1904, where he later went to school before proceeding to the Ewing Christian College, Allahabad, in 1921, graduating in 1925. Here, ably influenced and guided by the late Dr. Winfield Dudgeon, an American missionary teacher, he took his M.Sc. and D.Sc. degrees at the University of Allahabad in 1927 and 1931, respectively. Joining the staff of Agra College, Agra, in 1930, he became associate professor in 1936. Subsequent appointments were at the University of Allahabad (1937–39), Lucknow (briefly in 1939), and he became reader and head of the department of biology at the University of Dacca later the same year. The best-known period of his career began in 1949 when he was appointed professor and head of the Department of Botany at the University of Delhi, a post which he continued to hold until he died.

Maheshwari travelled widely. During his first visit to Europe in 1936–37 he was greatly inspired by meeting the eminent embryologist Professor Karl Schnarf of Vienna, who gave him the idea of writing *An Introduction to the Embryology of Angiosperms*, which was completed at Harvard University in 1945. He was a member of and held office in numerous scientific societies, but, of these, perhaps particular attention should be directed to the fact that he was president of the Indian Botanical Society in 1951 and became founder and first president of the International Society of Plant Morphologists in the same year. This last society is responsible for publishing the journal *Phytomorphology*, first issued in 1951 and of which Maheshwari has been the sole editor.

Maheshwari's *An Introduction to the Embryology of Angiosperms* has for many years been widely recognized as the leading textbook on the subject written in English, and a Russian translation has also been published. The more recent *Advances in the Embryology of Angiosperms*, edited by Maheshwari and published in 1963, is also widely used. It is impossible here to survey his numerous publications in scientific journals and it must suffice to say that until quite recently most of them fell into the broad field of descriptive morphology with special emphasis on the embryology of flowering plants, using the term embryology in the broadest possible sense. With his marked capacity for sifting and arranging factual information, Maheshwari, having mastered a wealth of detail, classified and clarified the main lines of variation in plant embryology that are known to occur. He also discussed the taxonomic and phylogenetic conclusions that can be drawn from embryological knowledge. In recent years he turned his attention to the experimental side of embryology, and some investigations on this important aspect were still in progress when he died.

Because of Maheshwari's influence, the study of plant embryology and floral morphology has assumed an important role in the development of botany in India in recent decades, especially among Ph.D. students. There may be some who feel that these research exercises have been too repetitive. It must be remembered, however, that theoretical conclusions based on descriptive aspects of botany are likely to be invalid unless they are supported by factual information drawn from investigations that are extensive and thorough. It was because Maheshwari realized that this is so, and because of his heavy teaching and administrative duties, that he adopted the only course open to him in seeking the aid of many collaborators and students to achieve his aim. The result must be judged from the synthesis of these exercises which Maheshwari achieved rather than on the individual researches themselves, however valuable these may be. Viewed in this light, Maheshwari's contribution to botany is a notable one, especially when we remember that he himself regarded his own work as only a part of the even broader synthesis of descriptive botany that will become possible when his contribution has been added to that of related morphological disciplines.

Maheshwari, who was married at the age of 13, is survived by his widow and by three sons and three daughters.

I thank Professor B. M. Johri and other colleagues of the late Professor Maheshwari for providing some of the particulars included in this notice.

C. R. METCALFE

INVERSE COMPTON EFFECT IN QUASARS

By M. J. REES and DR. D. W. SCIAMA
Department of Applied Mathematics and Theoretical Physics, University of Cambridge

THE importance of the inverse Compton effect in intense radio sources has been emphasized on several occasions[1-4]. In particular, Hoyle, Burbidge and Sargent have suggested[4] that Compton losses are so serious as to rule out some models for variable quasi-stellar sources (quasars) unless these objects are very much closer, and less luminous, than they would be if their red-shifts indicated a Hubble recession. The nature of the red-shifts of quasars has not yet been conclusively settled by observations, and therefore interest attaches to theoretical arguments which give any clue to this problem. In this article we present a further discussion of the effect of inverse Compton scattering, and hope to show that there are plausible models which assume that quasars are superluminous objects at cosmological distances.

Hoyle, Burbidge and Sargent considered a model for the variable part of 3*C* 273 with the following properties: (i) the radius of the region emitting the optical continuum is $\sim 10^{17}$ cm; (ii) the optical continuum is synchrotron radiation; (iii) all the electrons are accelerated within a volume with dimensions $\ll 10^{17}$ cm, and the radius of the source is determined by the distance which the radiating electrons can move before losing their energy.

Assumption (i) was adopted in view of the fact that the optical brightness of 3*C* 273*B* varies with a time-scale of a few months[5], and the light was assumed to be synchrotron radiation because of the observed optical polarization[6]. The variations are assumed to be caused by changes in the rate of production of relativistic electrons, and (iii) was adopted because of the difficulty of synchronizing the different parts of a larger region. We shall discuss this assumption later. We note, with reference to (ii), that polarized light could also be produced by inverse Compton scattering of polarized radio frequency radiation. We have previously[2] suggested a model in which the visible light is indeed produced in this way, and we shall discuss this possibility further in this article. (There is, incidentally, no evidence that the variable component of the light from 3*C* 273 is polarized.)

Hoyle, Burbidge and Sargent claimed that their assumptions could not be simultaneously satisfied if the power output has the value appropriate to a quasar at a cosmological distance. We shall show that their assumptions, strictly interpreted, do not in fact permit models of quasars even if they are "local" objects. However, we shall argue that assumption (iii) is not physically reasonable, and that, if it is dropped and we take a plausible value for the size of the region where the electrons are accelerated, it is possible to interpret the optical continuum radiation from quasars such as 3*C* 273*B* as either synchrotron or inverse Compton radiation, even if these objects are at cosmological distances.

Estimates of the Importance of Inverse Compton Scattering

In Fig. 1 the quantity τ_{sync} (defined as c times the synchrotron lifetime) of electrons emitting synchrotron radiation at the optical frequency of $\sim 3 \times 10^{14}$ c/s is plotted as a function of magnetic field H. We also plot the radius $r_{\text{s.a.}}$ of a self-absorbed source emitting synchrotron radiation at a rate $\sim 10^{31}$ ergs/sec/(c/s) at this frequency (the intensity appropriate to 3*C* 273*B* if it is at a cosmological distance). If the electrons are all accelerated in a region which can be treated as a point, the larger of these two numbers will determine the radius of the source (if we neglect for the moment the effect of Compton losses). If $r_{\text{s.a.}} > r_{\text{sync}}$ the lifetime of the electrons will be prolonged by the reabsorption of synchrotron radiation, so they will be able to reach the boundary of the emitting region despite their very short synchrotron lifetimes.

The "Compton distance" r_{comp} is also plotted on the same diagram. We define this to be $c\tau$, where τ is the time in which an electron would lose half its energy as a result of inverse Compton collisions, if it moved in a radiation field with energy density equal to the mean synchrotron energy density within the source. If r_{comp} is less than the radius of the source, Compton losses will be important, and the model will need to be modified to take them into account.

The point emphasized by Hoyle, Burbidge and Sargent —that Compton losses are more important than synchrotron losses, and that source models of this kind calculated ignoring the Compton effect are consequently not self-consistent—is shown clearly by the diagram, because r_{comp} is much less than the radius of the source for any reasonable value of the magnetic field strength. If the magnetic field were tangled, the source radius might be $\ll r_{\text{sync}}$ when there is no self-absorption. The discrepancy between r_{comp} and the source radius would then be even larger. The effect of the inclusion of self-absorption, which was not taken into account by Hoyle, Burbidge and Sargent, is to reduce the disparity as the field becomes very strong, but H would have to become impossibly large before the discrepancy disappeared altogether.

At first sight it may seem surprising that the occurrence of self-absorption can reduce the importance of the Compton losses, as one might expect these to be even more

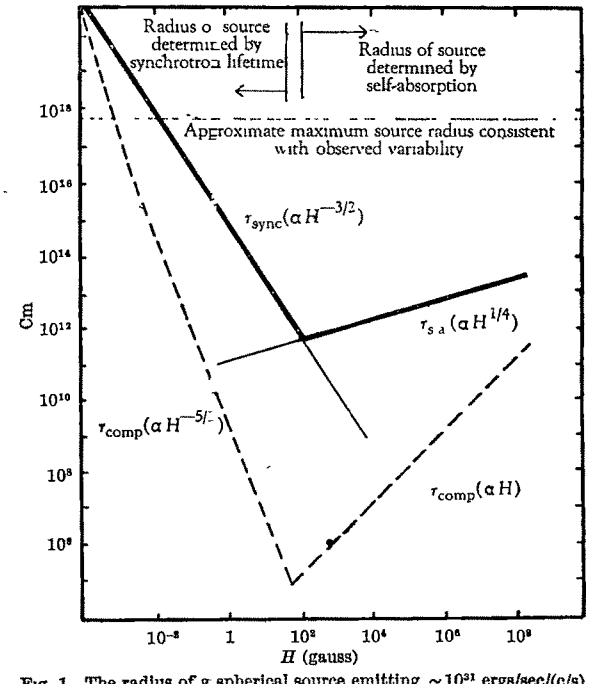

FIG. 1. The radius of a spherical source emitting $\sim 10^{31}$ ergs/sec/(c/s) at $\sim 3 \times 10^{14}$ c/s, in which the electrons are all assumed to be accelerated at its centre. The radius is approximately equal to the larger of r_{sync} and $r_{\text{s.a.}}$, where r_{sync} is c times the synchrotron lifetime of the appropriate electrons, and $r_{\text{s.a.}}$ is the radius of a self-absorbing source emitting the required flux. The graph also plots r_{comp}, which is defined to be the distance which the electrons would travel in a radiation field with the mean energy density of the synchrotron radiation within the source, before losing half their energy as a result of inverse Compton collisions. These quantities are only plotted for values of H for which the gyro-frequency of non-relativistic electrons is less than 3×10^{14} c/s. The small values which this graph gives for the source radius are not physically reasonable, for reasons which are given in the section headed "Dimensions of the Region where Electrons are Accelerated"

dominant if the net synchrotron radiation loss of the electrons is reduced. However, this is not so for two reasons: (i) the effect of self-absorption is to increase the dimensions of the source, and so reduce the radiation energy density; (ii) in a strong field the energy of the electrons which emit synchrotron radiation at a given frequency is less, and low energy electrons survive longer in a radiation field of given energy density.

If the electrons are all accelerated at the centre of the source, it is clearly not consistent to treat the Compton losses as a mere perturbation when r_{comp} is less than the source radius. Furthermore, we can easily see that no attempt to take the Compton effect properly into account can then lead to a consistent model, for the radius of such a model would obviously be smaller than the radius we calculated when we ignored Compton losses. The mean radiation density within the model would be correspondingly greater, and there would be an even greater discrepancy between the "Compton distance" and the source radius. If electrons were ejected from a negligibly small region, they would in fact radiate their energy predominantly in the form of γ-rays (produced as a result of repeated Compton scatterings) with energy comparable with that of the individual relativistic electrons. The radiation would come from a very small sphere opaque even to γ-rays, and a negligible fraction of the energy would be emitted at radio frequencies. Obviously such a source could not emit a detectable radio flux unless there were an absurdly high γ-ray flux.

It was stated by Hoyle, Burbidge and Sargent that this effectively rules out a model in which the optical frequency flux from a quasar such as 3*C* 273*B* results from Compton scattering of radio frequency photons by the same electrons which are responsible for the radio (synchrotron) emission. It is true that such models could not produce vastly more energy by the Compton process than by synchrotron emission without emitting unreasonably large amounts at X-ray and γ-ray frequencies by repeated scatterings. However, it is certainly possible for the two losses to be of comparable importance. One is encouraged to attempt to devise such a model for 3*C* 273*B* by the fact that the energy radiated in the optical continuum is almost certainly less than that emitted at radio frequencies $\lesssim 3 \times 10^{11}$ c/s (wave-lengths $\gtrsim 1$ mm). A model of this kind has been previously suggested by us[2], and also by Shklovski[3]. We shall later on describe such a model in greater detail, but Fig. 2 immediately suggests that such a possibility is likely to be quantitatively reasonable. Fig. 2 shows the same quantities as Fig. 1, but this time plotted for a source emitting synchrotron radiation with an observed intensity of ~300 flux units at 3×10^{11} c/s (which is consistent with Epstein's observations[7] of 3*C* 273 at millimetre wave-lengths). We see that the "Compton distance" exceeds the radius of the source when the field strength $\gtrsim 30$ G (and also when $H \lesssim 10^{-3}$ G, though we may ignore this case because the source would then be too large to exhibit rapid variations). We emphasize that this result is only obtained when allowance is made for synchrotron self-absorption. If the radius of the source were determined by the very short synchrotron lifetime of electrons in a field $\gtrsim 30$ G, the radiation density would be very high, and the Compton losses would be too great.

Dimensions of the Region where Electrons are Accelerated

In the preceding section it was assumed (following Hoyle, Burbidge and Sargent[4]) that Compton losses would not be serious if the Compton lifetime of electrons moving in a radiation field with the mean energy density of synchrotron radiation within the source exceeds the time they would take to cross the source. However, we shall show that, if the electrons all originate in a small region at the centre of the source, Compton losses are more important than this criterion would suggest. This is because the energy density of the scattered radiation is bound to exceed the synchrotron radiation density (implying that the model requires drastic modification) at points close enough to the centre, even if the original criterion indicates that Compton losses are not important.

If synchrotron self-absorption occurs, the energy density of synchrotron radiation will be almost uniform throughout the source. We can assume, as a rough approximation, that the electrons have a mean outward velocity ($\sim c$) which is independent of r. The electron number density will then be proportional to r^{-2}, and the rate of production of Compton scattered photons, per unit volume, will also be proportional to r^{-2}. Provided that the scattered photons escape from the source without undergoing further scattering, the energy density of the Compton scattered radiation within the source $\propto r^{-1}$. If, on the other hand, synchrotron self-absorption is negligible throughout most of the source, the synchrotron radiation energy density $\propto r^{-1}$ (implying incidentally that there must be a small self-absorbing region near the centre), and the Compton scattered radiation density will be $\propto r^{-2}$. In both these cases, therefore, the energy density of inverse Compton radiation relative to that of synchrotron radiation $\propto r^{-1}$. So however small this ratio at the boundary of the source, it will become large at points sufficiently near the centre. The model then becomes inconsistent, for the reasons discussed in the preceding section. It is therefore impossible to devise a model producing a significant amount of synchrotron radiation in which the relativistic electrons are assumed to originate at a point, even if r_{comp}, as defined earlier, is much greater than the source radius. This remark applies equally strongly if quasars are 'local' objects, and the required luminosity is comparatively low.

Other physical considerations obviously set lower limits to the size of the volume within which the relativistic electrons can be generated. The total energy which a quasar at a cosmological distance would radiate during its lifetime may well be in excess of 10^{60} ergs, and an object capable of liberating this amount of energy must have a very great mass. Because the Schwarzschild radius of a mass of, say, 10^{43} gm is $\sim 10^{15}$ cm, it is clear that the relativistic particles in a realistic model cannot be assumed to originate in a region many orders of magnitude smaller

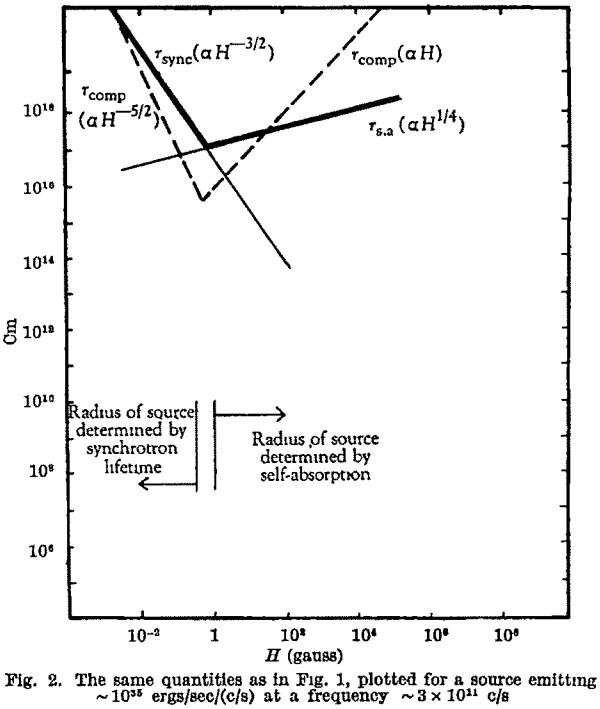

Fig. 2. The same quantities as in Fig. 1, plotted for a source emitting $\sim 10^{35}$ ergs/sec/(c/s) at a frequency $\sim 3 \times 10^{11}$ c/s

than the whole variable source. The larger this region has to be, the more difficult it becomes to synchronize variations in the rate of electron production over the whole volume. (It was for this reason that Hoyle, Burbidge and Sargent preferred not to assume that the electrons were being accelerated throughout the source.) We shall suggest in the next section some possible models.

Models for 3C 273 and Similar Variable Quasars

The first point to be made is that there *are* reasonable models capable of accounting for the optical variability of quasars on the assumption that they are at cosmological distances, and that the optical continuum is synchrotron radiation. For example, if the particles are being accelerated throughout a sphere of radius $\sim 10^{16}$ cm containing a magnetic field $\gtrsim 100$ G, the synchrotron lifetime of electrons radiating at visible frequencies will be shorter than the Compton lifetime (though these will both be much shorter than the time it would take for an electron to cross the source). The Compton losses will therefore be comparatively unimportant.

But there are also possible models in which the optical flux results from Compton scattering. If the observed flux at 3×10^{11} c/s (~ 300 flux units) is synchrotron emission, Fig. 2 shows that the dimensions of the emitting region must be $\sim 5 \times 10^{17}$ cm if $H \sim 100$ G. The electrons responsible for this synchrotron radiation will have $\gamma \sim 50$, and the radiation produced when such electrons scatter millimetre wave-length photons will be in the optical range. The observed flux density of the optical continuum is $\sim 0{\cdot}03$ flux units[8,9], so the energy radiated in this range is ~ 10 per cent of the total emission at frequencies $\lesssim 3 \times 10^{11}$ c/s (allowing for the factor $\sim 10^3$ difference in the frequency ranges). Using this fact we can easily determine the minimum size of the region within which the electrons are accelerated. We require the ratio of the Compton to synchrotron energy densities to be $\sim \frac{1}{10}$ at the boundary of the source ($\sim 5 \times 10^{17}$ cm radius). This ratio rises like r^{-1} within the source, and within an energetically reasonable model it must not become $\gg 1$. Therefore, we must take the dimensions of the region where the electrons are accelerated to be $\gtrsim 5 \times 10^{16}$ cm (see Fig. 3). Is this region too large to vary synchronously in time-scales of a few months? Fortunately not, because if the magnetic field strength ~ 100 G, the Alfven speed $\gtrsim c/10$ provided that the gas density $\lesssim 10^9$ atoms/c.c. This is an entirely reasonable requirement, and indeed unless the gas density were less than this the ionization losses would be so great as to prevent the acceleration of the electrons. The total energy in the magnetic field $\sim 10^{57}$ ergs, which is plausible on energetic grounds.

It follows from the usual self-absorption arguments that the radio flux at frequencies $\ll 3 \times 10^{11}$ c/s cannot come from the same small volume as the higher frequencies. The variable component of the flux observed[10–12] at frequencies $\gtrsim 1{\cdot}4 \times 10^9$ c/s would be emitted in a region a few parsecs in radius, as we have discussed in previous papers[2,13], and the non-varying low frequency flux could of course come from an even larger region (in which $H \ll 100$ G). The existence of lines in the optical spectrum of *3C 273B* implies the presence of excited gas, which is likely to be in the form of a shell surrounding the intense source of the continuum radiation[2,8,14,15], in which case it would absorb energy at optical and radio frequencies from the interior.

The inverse Compton effect plays an important part in quasars, and restricts the properties of permissible models. If the relativistic electrons are accelerated throughout a sphere of radius 10^{16}–10^{17} cm, there are models in which the optical continuum can result from either synchrotron or inverse Compton emission. The magnetic field in such models ~ 100 G, and the Alfven velocity in such a strong field will be so high ($\gtrsim c/10$) that

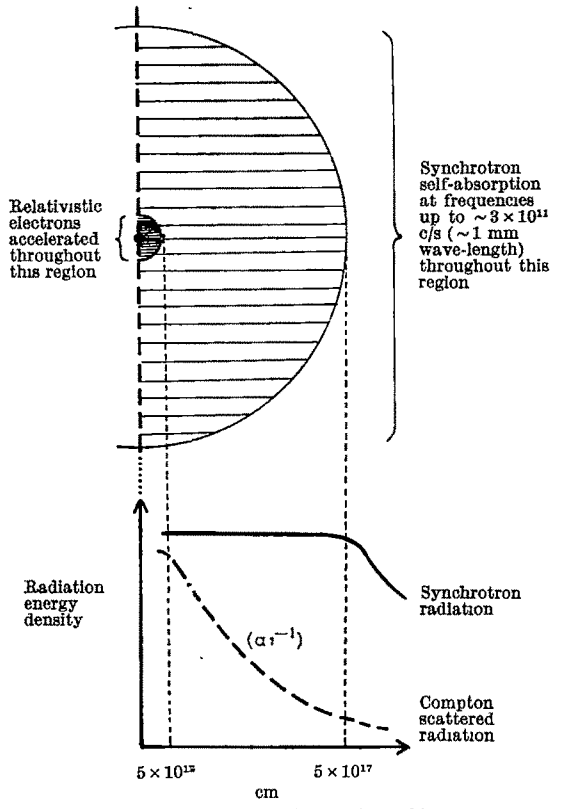

Fig. 3. A model for the central part of *3C 273B* in which the optical continuum arises from inverse Compton scattering of radio frequency synchrotron radiation, $H \sim 100$ G, and the particles are accelerated in a sphere of radius $\sim 5 \times 10^{16}$ cm which contains a massive object. The observed flux at $\sim 3 \times 10^{11}$ c/s (~ 1 mm wave-length) comes from a sphere of radius $\sim 5 \times 10^{17}$ cm. The ratio of the energy densities of synchrotron radiation and visible light is 10 : 1 at the outside, but increases to about 1 : 1 at the surface of the inner sphere. The radio flux observed at frequencies of less than 3×10^{11} c/s must come from a larger volume

the variations in the rate of acceleration of particles could be synchronized over a region of the required size in such a way as to give rise to the observed variations. It would be difficult to distinguish observationally between these two alternatives. If the "local" theory is adopted, the radiation density within the variable part of the quasar can be reduced by a large factor, and this obviously simplifies the construction of a model. However, we believe that there are no compelling arguments which force us to abandon the cosmological hypothesis.

Note added in proof. Optical observations of *3C 273* by J. B. Whiteoak (*Z. Astrophys.*, **64**, 181; 1966) cast doubt on the reality of the linear polarization reported in ref. 6. Although polarization of the optical continuum would strongly suggest that some of the light was synchrotron or inverse Compton radiation, this hypothesis would remain very probable even if the light from quasars were found to be unpolarized.

MILLISECOND RADIO PULSES FROM JUPITER

By DR. E. E. BAART*, C. H. BARROW and R. T. LEE
Radio Observatory, Department of Physics, The Florida State University, Tallahassee, Florida

AN experiment has been conducted to study the characteristics of the very short duration pulses which are sometimes observed in the decametre wave radiation from Jupiter. These pulses have been observed on a number of occasions during the 1965–66 apparition. Preliminary results indicate that the occurrence probability of this type of radiation is related to the System III Central Meridian Longitude (1957·0) somewhat differently from the more normal type of radiation, being relatively larger for the subsidiary sources *B* and *C* than for the main source *A*. Furthermore the correlation with satellite Io is more pronounced for events containing the short pulses than for other events.

The bursts of radiation from Jupiter usually have durations of between 0·2 and 10 sec with a gradual rise and fall in intensity and a fairly smooth profile. Following the *Recommendations for Standardization of Reporting Procedures*[1] recently proposed, *S*, *N* and *L* type bursts can be distinguished as defined in Table 1. Several observers[2–6] have reported receiving bursts with durations of the order of milliseconds, and for the purpose of discussing these another class of bursts, *I*, is arbitrarily defined having durations less than 50 msec. These latter pulses have sometimes been referred to as "spitting" pulses in the literature.

Table 1. BURST CLASSIFICATION

Character of emission		Suggested	
Burst type	Time scale in seconds	NASA classification	Name
Very short	Less than 0 05	1	*I**
Short	0 05–0·2		*S*
Normal	0 2–2 0	2	*N*
Long	Greater than 2 0	3	*L*

* Arbitrarily assigned for this article.

Observations have been made of the left- and right-handed components of the radiation at 16, 18 and 22 Mc/s, and of the total power at 14 Mc/s. The polarization measurements have been made using the method of Barrow[7] utilizing crossed five-element Yagi antennae, hybrid rings and separate receivers for the two senses of polarization to avoid the uncertainties that might arise from switching techniques. Identification was by normal aural monitoring techniques[8], but in addition the total power was recorded at 18 Mc/s using a broadside array having a null in the direction of Jupiter. This antenna served as a monitor to help discriminate static pulses which might have the same appearance as Jovian *I*-pulses. A phase-switched interferometer was operated at 18 Mc/s throughout observing periods as a further means of identifying that Jupiter was active during the period. The outputs of the polarimeters, the 14 Mc/s receiver and the 18 Mc/s null receiver were recorded by an eight channel electric writing high speed recorder using chart speeds of up to 50 mm/sec and post-detection time constants down to 5 msec. Most of the recordings of storms containing significant numbers of *I*-pulses were made using a time constant such that the minimum measurable pulse width at half-height was 7 msec. The reception of faint stations was eliminated by manually tuning the receivers over about 100 kc/s whenever signals were received. Static pulses were easily identified by their wide bandwidth and lack of polarization. The null monitor antenna and the interferometer were primarily for increasing confidence in the identification.

* On leave from the Department of Physics, Rhodes University, Grahamstown, South Africa.

Jupiter radio storms were observed on ninety-two occasions on 62 days during the period November 21, 1965–March 17, 1966. The burst structure showed a continuous range extending from the slowly varying *L*-bursts lasting for tens of seconds to isolated *I*-pulses with durations of 10 msec or less and separations of the order of a second. About half the storms included a few *N*- and *L*-bursts present with *I*-pulses superimposed. These *N*- and *L*-bursts were usually among the most intense in the storm and the *I*-pulses were seldom present for more than 1 or 2 min.

There were eighteen storms which contained appreciable *I*-pulse activity. In sixteen of these storms *I*-pulses occurred for at least 15 min and the *I*-pulses were as intense as, or more intense than, any *N*- or *L*-bursts which might have been present at the same frequency. On occasions, the *I*-pulses were isolated as in Fig. 1 but as the storm progressed they tended to cluster together so that the envelopes of their peaks looked like *N*-bursts. Frequently they seemed to have such short separations (10 msec or less) that the recorder pen would not return to its zero level between pulses. On many occasions *I*-pulses were present on one frequency while *N*-bursts were present on others. On these occasions, however, the profiles of the *N*-bursts were usually very irregular. Two sections from one of these *I*-pulse storms are shown in Figs. 2 and 3. In Fig. 2 there is strong *I*-pulse activity at 22 Mc/s which exhibits both senses of polarization with mostly *N*-bursts at 14, 16 and 18 Mc/s. There is no activity on the left-hand 16 Mc/s channel. In Fig. 3, 17 min later, *I*-pulses continue on the 22 Mc/s right-hand channel but there is little or no activity on the left-hand channel. At 16 and 18 Mc/s the activity is confined to *S*- and *N*-bursts with very weak left-hand channel activity at 18 Mc/s but appreciable left-hand channel activity at 16 Mc/s. *N*-bursts are also present at 14 Mc/s. It is clear that both the burst structure and the polarization can vary considerably from one frequency to another during a single event. The *I*-pulses were usually not present for the entire period of the storm. In most cases they were preceded or succeeded by *N*- or *L*-bursts on the same frequency. This behaviour is summarized in Table 2 which shows the System III (1957·0) longitudes for which the *I*-pulse storms were observed.

A histogram of a number of events against System III (1957·0) longitude is shown in Fig. 4 for all the storms observed. Observations at all frequencies have been combined for this purpose. Also shown in Fig. 4 is a similar histogram for periods of *I*-pulse activity only. The histogram for all the storms has the typical shape

Table 2. SYSTEM III (1957·0) LONGITUDES FOR MAJOR *I*-PULSE EVENTS

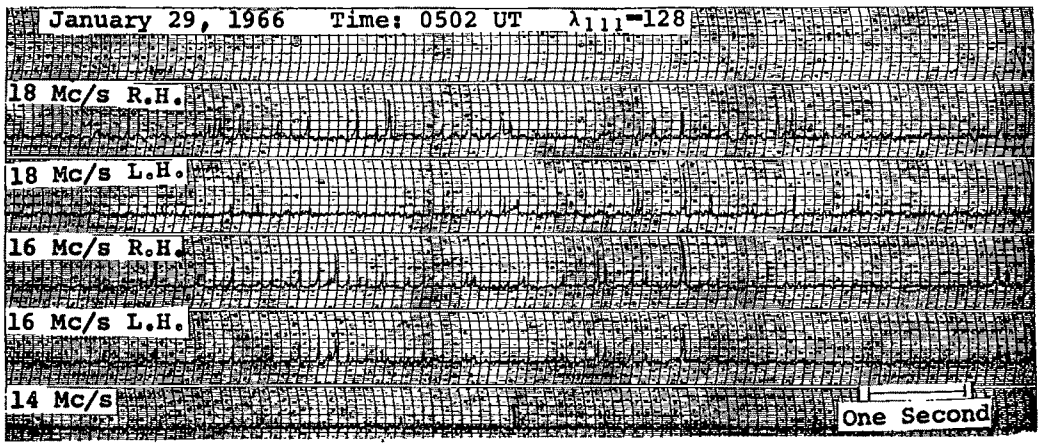

Fig. 1. Specimen record showing isolated *I*-pulses at 16 and 18 Mc/s

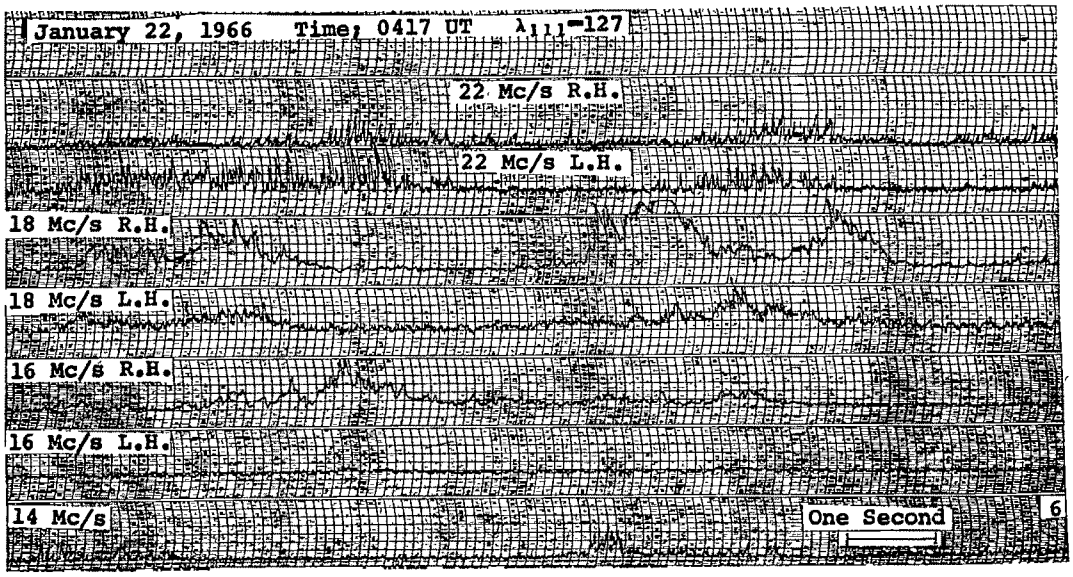

Fig. 2. Specimen record showing strong *I*-pulse activity at 22 Mc/s with *N*-bursts at 16 and 18 Mc/s

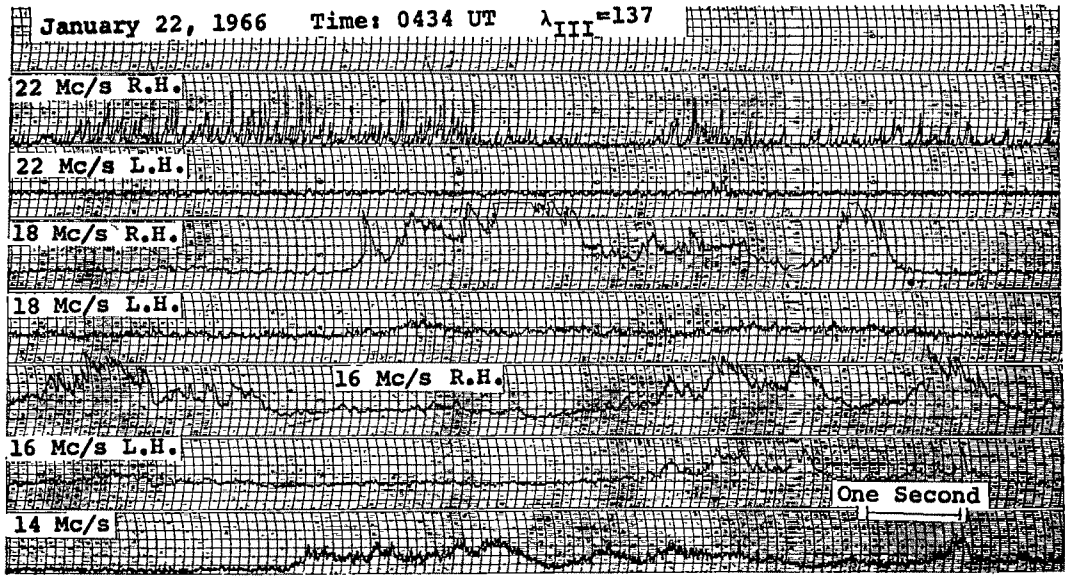

Fig. 3. Specimen record showing *I*-pulses at 22 Mc/s simultaneously with *L*- and *N*-bursts at 14, 16, and 18 Mc/s. Note the almost complete absence of activity on the left-hand channels at 22 and 18 Mc/s compared with 16 Mc/s and compared with the section of record taken 17 min earlier in Fig. 2

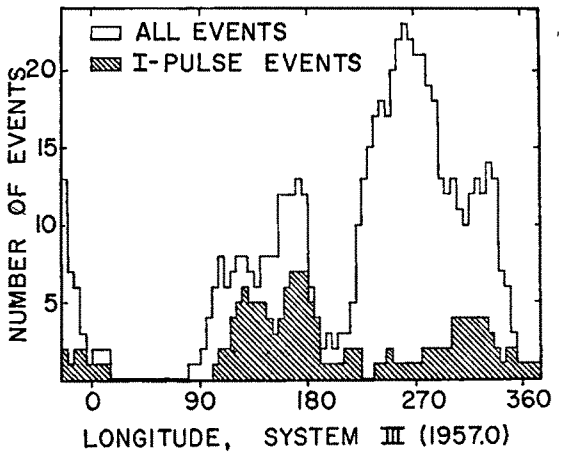

Fig. 4. Histogram of a number of events against System III (1957·0) longitude for all events and for *I*-pulse events only

observed in previous years with "sources" *A*, *B* and *C* defined by longitudes 190°–280°, 70°–190° and 280°–360° (ref. 1), respectively (sources *A* and *C* are unresolved). The interesting feature, however, is that most of the *I*-pulse storms are associated with sources *B* and *C* rather than source *A*.

Smith and Douglas[9] have suggested that *L* and *N* type burst structure may result from diffraction in the interplanetary medium. The present work suggests two possibilities. First, that the radiation associated with the *B* and *C* sources is produced within a smaller region than that from the source *A*, giving rise to a finer diffraction pattern which is produced by the interplanetary medium. (We thank Dr. W. C. Erickson for this suggestion.) The presence of *I*-pulses at one frequency and not at others may be an indication of the different depths and thus sizes of the source regions in the Jovian magnetosphere at which the different frequencies are produced. Alternatively, the *I*-pulse structure may be present in the radiation when it leaves Jupiter and not be produced during propagation through the interplanetary medium. Further study of *I*-pulses may thus prove valuable in clarifying the production mechanism of all Jovian decametric emission.

It is worth noting that, for the ninety-two events considered in this preliminary investigation, the correlation with satellite Io (ref. 10) is more clearly indicated for events containing *I*-pulses than for other events. More observations are required, however, to establish a conclusive result in this respect.

In conclusion, it might be appropriate to summarize the evidence that the *I*-pulse radiation originated from Jupiter. (*a*) The *I*-pulses formed an integral part of a Jupiter storm as identified by the usual techniques[8] and also by the 18 Mc/s phase-switched interferometer. The *I*-pulses were received on aerials pointing towards Jupiter but not on an aerial with a null in that direction. (*b*) The *I*-pulses were only observed as part of a normal Jupiter storm and were usually preceded and/or succeeded by *N*-bursts at the same frequency. The *I*-pulses usually clustered together so that the envelope of a group showed the form of an *N*-burst as in Figs. 2 and 3. They were usually accompanied by *N*- or *L*-bursts at other frequencies and less often by *I*-pulses at other frequencies. (*c*) The bandwidth of the *I*-pulses was always less than 4 Mc/s and individual pulses never occurred simultaneously on the different frequencies. A large proportion of the pulses were 100 per cent circularly polarized as shown in Fig. 3. Terrestrial static pulses have bandwidths considerably greater than 4 Mc/s and produce simultaneous pulses over a wide range of separated frequencies. Also, static is not polarized and does not occur in long series of closely spaced pulses of the type shown in Figs. 2 and 3. (*d*) The *I*-pulse radiation seems to be correlated with two central meridian longitude regions of Jupiter. Also, no *I*-pulse storms occurred when the central meridian longitude was between 20° and 100°.

In view of the foregoing it would seem to be most unlikely that these *I*-pulses were not connected with Jupiter in some manner.

We thank Mr. J. D. Merritt, Mr. D. P. Morrow and Mr. G. M. Resch for assistance with various phases of the work. The research is supported by the National Aeronautics and Space Administration.

RELATIVISTIC STATES OF POSITRONIUM AND STRUCTURE OF FUNDAMENTAL PARTICLES

By Dr. P. F. BROWNE
Faculty of Technology, University of Manchester

THERE is much to suggest that the interrelationship of the fundamental particles, which is the basic problem of particle physics, may turn out to be analogous to the interrelationship between the various atoms in the Periodic Table of the Elements. It has been too readily forgotten that the simple pictorial models of Rutherford and Bohr provided the key to a successful theory of atomic structure, and are probably indispensable as a conceptual guide for the application of wave mechanics. In this article my aim is to find an equivalent model for particle structure. The particle states will be distinguished from the atomic states in that they are relativistic.

Consider the relativistic positronium system, in which an electron and a positron rotate about their common centre of mass, *C*, with a velocity, *v*, which is close to the velocity of light, *c*. We shall adopt the rest frame of the centre of mass, *C*, the inertial frame. The radial distance to either particle will be denoted by *r*, so that the particles are separated by $2r$. The particles will be assumed to rotate about *C* in a common circular orbit at opposite ends of a diameter. The force exerted on either particle will be due to the time-symmetric (half-advanced and half-retarded) field of the other, since the particles do not radiate in stationary orbits.

We wish to calculate the fields of the positron at the position of the electron. If the positron were at rest in the inertial frame then the required field would be simply the electric field, $\mathbf{E}' = e2\mathbf{r}'/(2r')^3$. In a frame of reference in which the positron moves with velocity $\mathbf{v}$ in a direction normal to $\mathbf{r}'$, let the electric and magnetic fields be $\mathbf{E}$ and

H respectively. Then from the transformation of fields[1] we know that:

$$\mathbf{E} = \gamma\mathbf{E}'; \quad \mathbf{H} = \gamma\mathbf{v} \times \mathbf{E}'/c \tag{1}$$

where $\gamma = (1 - v^2/c^2)^{-\frac{1}{2}}$. These fields will exert a Lorentz force on the electron, the instantaneous velocity of which is equal and opposite to that of the positron. Noting that $\mathbf{H} = \mathbf{v} \times \mathbf{E}/c$ according to equation (1), we obtain:

$$\mathbf{F} = -e(\mathbf{E} - \mathbf{v} \times \mathbf{H}/c) = -e[\mathbf{E} - \mathbf{v} \times (\mathbf{v} \times \mathbf{E})/c^2] = \frac{e^2\gamma(1 + v^2/c^2)\mathbf{r}}{4r^3} \tag{2}$$

where we have used $\mathbf{r}' = \mathbf{r}$. We assume that this force law is valid instantaneously in the case of circular motion ($v = \omega r$).

The question of the magnetic interactions between the particles such as spin$_1$–orbit$_1$, spin$_1$–orbit$_2$, spin$_1$–spin$_2$, or orbit$_1$–orbit$_2$, requires a brief digression. Let us adopt the attitude that the Bohr–Sommerfeld (B–S) theory has the status of an alternative language to quantum theory in the sense that every phenomenon will have a description in either language. We contend that with suitable generalization, B–S theory is capable of yielding predictions to any required accuracy. We view the B–S quantization rules as boundary conditions which are imposed on a continuum of classical field momentum-energy by the act of measurement. The field will satisfy Maxwell's equations, generalized by introduction of the non-linear term $T^{\alpha\beta}v_\beta$ in the source current density, where $T^{\alpha\beta}$ is the Maxwell tensor for the field and v_β is the 4-velocity of the charge the motion of which is being considered. It is in respect of the non-linearity of the generalized classical field that the deviation with quantum electrodynamics occurs, because in the latter theory linear superposition of states is an axiomatic postulate. The postulate leads to great simplifications (particularly in many electron systems), but it is achieved at the expense of having to introduce operator algebra. Thus in the Jordan–Wigner quantum field version of electrodynamics, the wave-function is not a classical field variable only because it is subject to anticommutation rules. These rules are a direct expression of the Pauli Principle, so that this Principle may be regarded as a consequence of the artificial linearization of the "field", and it will not be required in classical field cum B–S theory.

To return to the question of magnetic couplings, we know that spin effects were first introduced in quantum theory by means of the Pauli spin matrices as an empirical "extra" to Schrodinger's wave mechanics. Later the spin effects emerged automatically from Dirac's relativistic wave mechanics. We expect the same to happen in the classical field cum B–S language; that is, spin effects may be introduced either as an extra to a non-relativistic theory or they may emerge automatically from relativistic equations.

The former type of approach is well recognized. By imagining a spinning sphere with charge distributed uniformly over the surface the combination of magnetic and electric fields gives rise to electromagnetic momentum which bears a ratio to the magnetic moment of one-half the ratio for orbital revolution. If the angular momentum of the spinning electron is **S**, then the magnetic moment is $\mu = (e/mc)\mathbf{S}$. The spin–orbit coupling can now be derived. In the rest frame of the electron the electric field of the nucleus, **E**, is transformed into the magnetic field, $\mathbf{H} = \mathbf{v} \times \mathbf{E}/c$, which interacts with the moment to give the coupling energy $\boldsymbol{\mu}.(\mathbf{v} \times \mathbf{E}/c)$. To see how this energy is transformed when we return to the rest frame of the nucleus we express it in the form $\boldsymbol{\omega}_L.\mathbf{S}$, where ω_L is the Larmor precessional frequency of the moment about the field **H**. On transforming back to the rest frame of the nucleus there arises in addition to the orbital motion of the electron the Thomas precession, $\boldsymbol{\omega}_T = -(\mathbf{v} \times \mathbf{a})/2c^2$, which has to be added to the Larmor precession (**a** is the acceleration of the electron). Inserting $\mathbf{a} = -\mathbf{E}e/m$, we see that $\boldsymbol{\omega}_T = -\frac{1}{2}\boldsymbol{\omega}_L$. Hence the spin–orbit coupling becomes $\frac{1}{2}\boldsymbol{\mu}.(\mathbf{v} \times \mathbf{E}_r c)$ (ref. 2). For the case of an observer who chooses to remain in the rest frame of the nucleus, the coupling arises from the interaction of **E** with an electric moment of the electron. The electric moment arises because the relativistic addition of the orbital and spin velocities of the charged sphere gives the sphere a distorted appearance causing the centre of charge to be displaced from the centre of mass. Since the charge is piled up on the side with the highest velocity and reduced on the other side, the spin axis of the electron tends to align itself normally to **E** and **v** (in order to maximize coupling energy). It can be shown that the orbital and spin moments precess about the direction of the resultant moment[3].

The second type of approach is well exemplified by the famous Bohr–Sommerfeld treatment of the relativistic hydrogen atom. This treatment, it will be recalled, was actually superior to the early Schrodinger wave mechanics, and the agreement of the result with that of Dirac's wave mechanics is described by Eisberg (ref. 2, page 356) as "one of the most amazing coincidences to be found in the study of physics". We contend that the result is not a coincidence, but that because the theory is relativistic, spin–orbit coupling is implicitly taken care of (without introduction of any spin parameter). In the same way spin effects will emerge from our relativistic equations. It would be superfluous and wrong to add terms to describe magnetic interaction.

With this justification for the force law (2), we proceed to equate it to relativistic centrifugal force, obtaining:

$$\frac{-e^2}{(2r)^2}\left(1 + \frac{v^2}{c^2}\right) = \frac{\gamma mv^2}{r} \tag{3}$$

For the case of a circular orbit without precessional periods, the B–S quantization rules yield:

$$2\gamma mvr = n\hbar \tag{4}$$

Eliminating mr between equations (3) and (4), we obtain:

$$4\eta^2\gamma^4 - (4\eta^2 + 1)\gamma^2 + (\eta^2 + 1) = 0 \tag{5}$$

where:

$$\eta = \frac{1}{2\pi}\left(\frac{e^2}{\hbar c}\right) = \frac{\alpha}{2n} = \frac{1}{274n} \tag{6}$$

The quadratic equation (5) has the two solutions:

$$\gamma_1^2 = \frac{1}{8\eta^2}[(4\eta^2 + 1) - (1 - 8\eta^2)^{1/2}] \simeq 1 + \eta^2 \tag{7a}$$

$$\gamma_2^2 = \frac{1}{8\eta^2}[(4\eta^2 + 1) + (1 - 8\eta^2)^{1/2}] \simeq \frac{1}{4\eta^2} - \eta^2 \tag{7b}$$

where we expand the square root term up to terms of order η^4 in the small quantity, η.
